# Cold-Formed Steel Frame and Beam-Column Design 

## RESEARCH REPORT RPO3-2

AUGUST 2003
REVISION 2006

Committee on Specifications
for the Design of Cold-Formed
Steel Structural Members

The material contained herein has been developed by researchers based on their research findings. The material has also been reviewed by the American Iron and Steel Institute Committee on Specifications for the Design of Cold-Formed Steel Structural Members. The Committee acknowledges and is grateful for the contributions of such researchers.

The material herein is for general information only. The information in it should not be used without first securing competent advice with respect to its suitability for any given application. The publication of the information is not intended as a representation or warranty on the part of the American Iron and Steel Institute, or of any other person named herein, that the information is suitable for any general or particular use or of freedom from infringement of any patent or patents. Anyone making use of the information assumes all liability arising from such use.

## PREFACE

This report is based on a thesis presented to the faculty of the Graduate School of Cornell University by Andrew T. Sarawit for the decree of Doctor of Philosophy.

The sponsorship of the Rack Manufacturers Institute and the American Iron and Steel Institute is gratefully acknowledged. The authors are also wish to thank Mr. James Crews, Mr. Daniel Clapp, Mr. John Nofsinger, and Dr. Helen Chen of the sponsoring organizations for their outstanding help through out the duration of the research.

# COLD-FORMED STEEL FRAME 

# AND BEAM-COLUMN DESIGN 

by<br>Andrew T. Sarawit ${ }^{1}$<br>Teoman Peköz ${ }^{2}$, Project Director

A Research Project Sponsored by
The American Iron and Steel Institute and The Rack Manufacturers Institute

1. Graduate Research Assistant - School of Civil and Environmental Engineering, Cornell University
2. Professor - School of Civil and Environmental Engineering, Cornell

## TABLE OF CONTENTS

1. Introduction ..... 1
1.1. Background ..... 1
1.2. Objectives and Scope ..... 2
1.3. Related Literature ..... 3
2. Column Bases ..... 5
2.1. Introduction ..... 5
2.2. Development of a Base Fixity Equation ..... 13
2.2.1. Contact Stresses Between Base Plate and Floor ..... 13
2.2.2. Normal Loads on the Boundary of Half-Space ..... 19
2.2.3. Base Fixity Charts ..... 29
2.3. Finite Element Analysis Verification ..... 30
2.4. Conclusions ..... 33
3. Beam to Column Connections ..... 34
3.1. Introduction ..... 34
3.2. Beam to Column Connection Tests ..... 35
3.3. Proposed Portal Test ..... 40
3.4. Finite Element Simulation of the Cantilever Test ..... 42
3.5. Conclusions ..... 48
4. Members ..... 49
4.1. Introduction ..... 49
4.2. Elastic Buckling Strength of Perforated Members ..... 50
4.3. Torsional-Flexural Buckling ..... 64
4.4. Effective Lengths ..... 73
4.5. Effective Design Area ..... 81
4.5.1. Stiffened Elements ..... 82
4.5.2. Unperforated Members ..... 86
4.5.3. Perforated Members ..... 95
4.6. Member Design Strength ..... 103
4.7. Effective Section Modulus ..... 113
4.8. Moment Magnification Factor ..... 116
4.9. Conclusions ..... 121
5. Cold-Formed Steel Frames ..... 124
5.1. Introduction ..... 124
5.2. Elastic Buckling Strength of Pallet Racks ..... 125
5.2.1. Effective Length $K_{x}$ ..... 125
5.2.2. Alignment Chart and Torsional-Flexural Buckling Provisions ..... 129
5.3. Plumbness ..... 132
5.4. Moment Magnification Factor ..... 135
5.5. Nonlinear Analysis of Pallet Racks ..... 139
5.6. Effective Length Approach and Notional Load Approach for Cold-Formed Steel Frame and Beam-Column Design ..... 143
5.6.1. Isolated Rotationally Restrained Sway Column ..... 148
5.6.2. Interaction Equation ..... 157
5.6.3. Cold-Formed Steel Frames ..... 160
5.6.4. Development of Approach $2 b$ ..... 172
5.6.5. Approach $1 a$ with $K_{x}=1.7$ ..... 174
5.7. Finite Element Simulation of Pallet Rack Test ..... 174
5.7.1. Beam Model ..... 179
5.7.2. Shell Model ..... 180
5.8. Conclusions ..... 184
6. Results and Conclusions ..... 186
Appendix A Column Bases ..... 191
Appendix B Base Fixity Charts ..... 202
Appendix C Thin-Walled Sections ..... 215
Appendix D Beam-Columns ..... 220
Appendix E Design Results ..... 223
Appendix F Design Examples ..... 290
Appendix G Pallet Rack Drawings ..... 297
Appendix H Computer Programs ..... 300
References ..... 327

## LIST OF TABLES

2.1 Column and Base Plate Dimensions in Study ..... 24
3.1 Beam to Column Connection Test Results ..... 44
4.1 Values of Plate Buckling Coefficients ..... 51
4.2 Section A-LDR Dimensions and Properties ..... 54
4.3 Section A-LDR-2 Dimensions and Properties ..... 55
4.4 Section A-HDR Dimensions and Properties ..... 56
4.5 Concentrically Loaded Compression Member Buckling Modes ..... 63
4.6 Flexural Member Buckling Modes ..... 63
4.7 Section Dimensions and Properties ..... 66
4.8 Boundary Conditions of the Open-section Beam Element for Elastic Buckling Problems ..... 67
4.9 Evaluation of the Torsional-Flexural Buckling Equation - Study II ..... 68
4.10 Evaluation of the Torsional-Flexural Buckling Equation - Study III ..... 69
4.11 Evaluation of the Torsional-Flexural Buckling Equation - Study IV ..... 70
4.12 Evaluation of the Torsional-Flexural Buckling Equation - Study V ..... 71
4.13 Values of Column $K_{y}$ and $K_{t}$ for Upright Frame A \& B ..... 75
4.14 Values of Column $K_{y}$ and $K_{t}$ for Upright Frame C \& D ..... 76
4.15 Values of Column $K_{y}$ and $K_{t}$ for Upright Frame E \& F ..... 77
4.16 Values of Column $K_{x}$ and $P_{e}$ for Upright Frame A, B, C, and D ..... 79
4.17 Values of Column $K_{x}$ and $P_{e}$ for Upright Frame E \& F ..... 80
4.18 Comparison Among the AISI Design Approach, the Modified AISI Design Approach, and the Analytical Results ..... 89
4.19 Stub-Column Tests and Analytical Results ..... 96
4.20 Evaluation of Sub-Column Flexural Strength ..... 115
5.1 Different Levels of Structural Analysis ..... 140
5.2 Boundary Conditions in Study ..... 150
5.3 Statistics for the Correlation of Design Procedures with the FEM Results ..... 150
5.4 Beam to Column Connection Stiffnesses in Study ..... 162
5.5 Load Case 1 - Statistics for the Correlation of Design Procedures with the FEM Results ..... 164
5.6 Load Case 2 - Statistics for the correlation of design procedures with the FEM Results ..... 165

## LIST OF FIGURES

## Chapter

## Introduction

### 1.1 BACKGROUND

The design of industrial steel storage racks presents several challenges to the structural engineer. Presently, the design in the United States is carried out according to the 1997 edition of the Specification published by the Rack Manufacturers' Institute (RMI). The RMI published its first "Minimum Engineering Standards for Industrial Storage Racks" in 1964.

The work that resulted in the first edition of the Specification was initiated by the RMI in 1972 at Cornell University. Several editions of the Specification have been prepared based on the work by the RMI Specification Advisory Committee and the researchers at Cornell University under the supervision of Professors George Winter and Teoman Peköz until 1979 and under the supervision of Teoman Peköz since 1979. The RMI (1997) Specification is tied closely to the AISI (1996) Specification for the provisions on Cold-Formed Steel Design.

### 1.2 OBJECTIVES AND SCOPE

The design of cold-formed steel frames and beam-columns used in industrial storage racks is complex because of the significant perforations in the columns, and the semi-rigid nature of the beam to column connections and column bases. In addition, the columns usually have open cross-sections, making it vulnerable to torsional-flexural buckling. Many assumptions are made in the current design specification to simplify the design procedures, and as a result the design becomes quite conservative. The objective of this research was to make improvements in the RMI (1997) Specification and the AISI (1996) Specification.

Numerical methods were used to carry out studies at both the component and the frame level, to verify or modify the current design provisions. At the component level, the topics focused upon are the column base fixity, the beam to column connection test procedure, and the design of perforated members. At the frame level, studies were carried out to evaluate the current effective length approach, and to examine the notional load approach as an alternative design procedure; as well as to use numerical methods for structural analysis, such as elastic buckling analysis and second-order elastic analysis considering semi-rigid connections. Studies are presented in this thesis for each of these components, and then followed by a study on coldformed steel frames.

### 1.3 RELATED LITERATURE

The work presented in this thesis would not be possible without studying previous works of other researchers. The following are some of the works which the author studied and referred to extensively throughout this research project.

Textbooks written by Galambos (1988), Hancock (1998), Peköz (1987), Rhodes (1991), Salmon and Johnson (1996), Timoshenko and Gere (1961), and Yu (2000) provided in depth explanations of the fundamental basis for the design of cold-formed steel and metal structures.

Studies given by Galambos (1960), and Salmon, Schenker and Johnston (1955) were the basis for the column base fixity equation used in the RMI specification. The author referred to the following solid mechanic textbooks: Gurtin (1981), Malvern (1969), Sokolnikoff (1983), Timoshenko and Goodier (1969) to solve column base fixity problems.

Beam-to-column connection test procedures given in the commentary section of the RMI specification were reviewed and used to develop a new alternative test procedure. These beam to column connection tests had been carried out extensively by Markazi, Beale, and Godley (1997), and Harris and Hancock (2002).

Journal papers by Stuto (1993), and White and Clarke (1997) thoroughly give the historical background, philosophies, and comparison between different standards for the design of steel beam-columns. And discussion by Peköz and Winter (1973) provide background information on the development of the RMI specification.

The influence that the semi-rigid nature of the beam to column joints and column bases have on the pallet racks stability were investigated by Baldassino and Bernuzzi (2000), Cheng (1973), and Lewis (1991). Salmon, Welch and Longinow (1973), and Godley (2002) investigated the behavior of drive-in and drive-thru storage racks; Olsson, Sandberg and Austrell (1999) investigated the influence of damage on
the load carrying capacity of storage rack columns; and Teh, Hancock and Clarke (2001) investigated the buckling behavior of high-rise storage rack structures.

Torsional-flexural buckling and moment magnification factor studies carried out in the thesis were based primarily on Peköz (1967), Peköz and Celebi (1969), and Salmon and Johnson (1996).

Comparison between the effective length approach and notional load approach for assessing frame stability has been and is continuously being studied by the ASCE Task Committee on Effective Length. The author has referred to their ASCE (1997) report and is very grateful for their collaboration making the study on Effective Length Approach and Notional Load Approach for Cold-Formed Steel Frame and BeamColumn Design in this research project possible.

Previous researchers at Cornell University have studied the finite element modeling assumptions of cold-formed steel members extensively. The analytical studies carried out in this research project would not be possible without reference to the finite element studies conducted by Schafer and Peköz (1998), and Schafer (1997).

The several computer programs that the author developed for this research project were based on the theory of structural analysis given by Chen and Atsuta (1976), Gattass and Abel (1987), Huebner, Thornton and Byrom (1995), Gotluru (1998), McGuire, Gallagher and Ziemian (2000), Timoshenko and Gere (1961), Yang (1986), as well as the cold-formed steel design approaches given by AISI (1996), Schafer (1997), and Schafer and Peköz (1999).

The author is certain that many more researchers other than those mentioned here contributed to the research and development of cold-formed steel frame and beam-column design. These omissions are either for the sake of brevity or because they were unknown to the author.

## 2

## Column Bases

### 2.1 INTRODUCTION

Storage rack stability depends significantly on the conditions of the column bases. The RMI specification uses the following base fixity expression, for the ratio of the moment with respect to the corresponding rotation of the base to account for the semi-rigid nature of the connection of the column to the floor as

$$
\begin{equation*}
\frac{M}{\theta}=\frac{b d^{2} E_{c}}{12} \tag{2.1}
\end{equation*}
$$

where $b$ is the width of the column parallel to the flexural axis, $d$ is the depth of the column perpendicular to the flexural axis, and $E_{c}$ is the modulus of elasticity of the floor, which is assumed to be concrete. The expression above is based on an analytical approximation developed by Salmon, Schenker and Johnston (1955) for the case where the footing does not rotate in soil, which is the case for the storage racks in this study. Rotation takes place between the column ends and the floor due to the deformation of the base plate, the anchor bolts, and the concrete. Salmon, Schenker and Johnston (1955) also developed a method for finding the moment-rotation
relationship by analyzing the behavior of such anchorages in five different stages starting with a trapezoidal stress distribution in the concrete floor under the base plate and ending at the failure of the anchor bolts. The RMI specification considered only the first stage.

The connection between the column and the floor could be represented in an analytic frame model either by a torsional spring or by inserting an equivalent floor beam between the column bases. The stiffness of the equivalent floor beam that would provide the same restraints as Eq. (2.1) could be found from basic structural analysis. Consider a beam element shown in Fig. 2.1 $a$ with its two ends identified as $a$ and $b$. The bending moments at the two ends are

$$
\begin{align*}
& M_{a}=\frac{4 E I}{L} \theta_{a}+\frac{2 E I}{L} \theta_{b}+\frac{6 E I}{L^{2}} u_{a}-\frac{6 E I}{L^{2}} u_{b}  \tag{2.2}\\
& M_{b}=\frac{2 E I}{L} \theta_{a}+\frac{4 E I}{L} \theta_{b}+\frac{6 E I}{L^{2}} u_{a}-\frac{6 E I}{L^{2}} u_{b} \tag{2.3}
\end{align*}
$$

where $u_{a}$ and $u_{b}$ are the translation degrees of freedom, $\theta_{a}$ and $\theta_{b}$ are the rotational degrees of freedom, $L$ is the length, $I$ is the moment of inertia, and $E$ is the modulus of elasticity of the beam element. To determine the stiffness of the equivalent floor beam for rack not braced against sidesway, consider a frame that has its column bases rotate equally because of the sidesway as shown in Fig. 2.1b, the boundary conditions of segment $a b$ in this case are $M_{b}=0, u_{a}=0$, and $u_{b}=0$. Using Eqs. (2.2) and (2.3) with these boundary conditions $M_{a}$ is obtained as follows:

$$
M_{a}=\frac{6 E_{s} I_{f}}{L_{f}} \theta_{a}
$$

the resisting moment that is developed in the interior column base from the two ends of the equivalent floor beam is $M=2 M_{a}$ that is

Figure 2.1 (a) Beam element (b) Equivalent floor beam for rack not braced against sidesway (c) Equivalent floor beam for rack braced against sidesway

$$
\begin{equation*}
M=\frac{12 E_{s} I_{f}}{L_{f}} \theta \tag{2.4}
\end{equation*}
$$

where $\theta$ is the angle of rotation of the column base which is equal to $\theta_{a}$. Inserting the above equation in Eq. (2.1) and assuming $E_{s} / E_{c}=10$ we have the stiffness of the equivalent floor beam for rack not braced against sidesway as given in the RMI specification.

$$
\begin{equation*}
\frac{I_{f}}{L_{f}}=\frac{b d^{2}}{1440} \tag{2.5}
\end{equation*}
$$

To determine the stiffness of the equivalent floor beam for a rack braced against sidesway the same procedure is used, however, as shown in Fig. 2.1c the boundary conditions of segment $a b$ in this case are $M_{b}=-M_{a}, u_{a}=0$, and $\theta_{b}=0$. Using Eqs. (2.2) and (2.3) with these boundary conditions $M_{a}$ is obtained as follows:

$$
M_{a}=\frac{2 E_{s} I_{f}}{L_{f}} \theta_{a}
$$

the resisting moment that is developed in the interior column base at the two ends of the equivalent floor beam is $M=2 M_{a}$ that is

$$
\begin{equation*}
M=\frac{4 E_{s} I_{f}}{L_{f}} \theta \tag{2.6}
\end{equation*}
$$

Inserting the above equation in Eq. (2.1) and assuming $E_{s} / E_{c}=10$ we have the stiffness of the equivalent floor beam for rack braced against sidesway as given in the RMI specification.

$$
\begin{equation*}
\frac{I_{f}}{L_{f}}=\frac{b d^{2}}{480} \tag{2.7}
\end{equation*}
$$

The effective length factor for the portion of the column from the floor to the first beam level could then be found from the alignment chart with the following:

$$
\begin{equation*}
G_{b}=\frac{I_{c} / L_{c 1}}{2\left(I_{f} / L_{f}\right)} \tag{2.8}
\end{equation*}
$$

where $I_{c}$ is the column moment of inertia and $L_{c 1}$ the distance from the floor to the first beam level.

Several analytical models of the base fixity problem were studied. Details of their derivation can be found in Appendix A. The first model shown in Fig. 2.2 consists of a series of springs to represent the concrete floor. If the stiffness of these springs is set to $k=E_{c} / d$ the base fixity is found to be the same as in Eq. (2.1). The second model shown in Fig. 2.3 is similar to the first model, that is considering only the concrete block under the base plate, but instead of springs the second model uses the beam theory approach with the same result obtained if $\alpha=d$ where $\alpha$ is the depth of the concrete block. A third model uses a basic solid mechanic approach to understand better how the concrete block in the first two models deforms. Starting from a defined stress field and boundary conditions, the displacement field could be found for the concrete block as shown in Fig. 2.4.

Considering only the concrete block under the base plate, however, results in a lower stiffness than what the actual floor could develop; this is because the confinement from the surrounding material was neglected. The concrete floor should instead be represented with a half-space material. Based on this idea a fourth model was studied where it is a two-dimensional elastostatic problem with normal loads on the boundary of half-space. By superimposing some combinations of Figs. $2.5 a$ and $2.5 b$, a bending load distribution indicated in Fig. $2.5 c$ can be obtained. Once the applied load is defined the displacement field can be found. The deformation of the concrete surface under the applied load region is shown in Fig. 2.6. Although the fourth model is only a plane strain problem and may not represent the actual three

Figure 2.7 Model 5 (a) Square base plate (b) 2 by 1 Rectangular base plate
dimensional base fixity problem, it can be seen that the surrounding concrete does affect the surface displacement thus differing from the previous models.

Finally, the fifth model not only considered the half-space nature of the floor, but it also considered the three-dimensional aspect of the problem. This model is considered to be better than all the previous models to represent the base fixity problem. Normal loads were applied on the boundary of the concrete floor and the resulting displacement was determined. When a square base plate was considered in this model, normal load distribution $p$ was applied and the surface deformation was obtained as shown in Fig. 2.7a. The resulting base fixity was 4.05 times higher than Eq. (2.1). For a 2 by 1 rectangular base plate, the results showed that the stiffness was 5.128 times higher than Eq. (2.1). This confirms that the current base fixity equation may be underestimating the actual stiffness. However, defining contact pressure between the base plate and concrete surface as a linear bending load distribution must be justified. This motivated the study described in Section 2.2. By using the fifth model approach but with improvement in defining the normal load, a new base fixity equation was developed.

### 2.2 DEVELOPMENT OF A BASE FIXITY EQUATION

### 2.2.1 Contact Stresses Between Base Plate and Floor

The objective here was to study how the load is transferred from the column to the floor. Once the load distribution on the concrete surface is known, the surface deformation can be found by an approach similar to the fifth model approach and thus the base fixity can be obtained. The load distribution on the concrete surface must be solved from a contact simulation between the base plate and the floor. The finite element method was used to solve this problem. Since the columns in consideration
are thin-walled sections, namely, the column wall thickness $t_{w}$ and base plate thickness $t_{p}$ both are relatively small compared to the width or depth of the column, the problem was simplified by solving each wall section separately with a plane strain analysis. Two cases were considered, one when the column wall section is positioned at the edges of the base plate as shown in Fig. 2.8 and the other when it is at the center as shown in Fig. 2.9.

Finite element assumptions are as follows: The four node plane strain elements were used to model. Contact surfaces were defined between the base plate and the concrete to simulate their interaction. However, in this study no friction was considered between the two surfaces. In addition, since the floor was assumed to be a half-space and only a small region of the base plate was considered, plane strain infinite elements were needed to model the far-field region of the concrete and base plate. For the case when the column wall section is positioned at the middle, because it is a symmetric problem only a half model is needed as shown in Fig. 2.9. The material model used for the column wall and base plate was elastic with $E_{s}=29500 \mathrm{ksi}$ and $v=0.3$ while the concrete was assumed elastic with $E_{c}=2950 \mathrm{ksi}$ and $v=0.2$. A uniform compression stress was applied at the top of the column wall.

A parametric study was carried out for the two cases to find out how the contact stress distribution changes as the base plate to column wall thickness ratio, $t_{p} / t_{w}$ is varied from 1 to 3 . The normal load distribution on the concrete surface was obtained and plotted as shown in Figs. 2.10 and 2.11. The vertical axis represents the stress intensity factor $\sigma_{c} / \sigma_{w}$, where $\sigma_{c}$ is the stress on the concrete surface, and $\sigma_{w}$ is the applied stress on the column wall. The horizontal axis represents the normalized position across the concrete surface. As seen in both cases as the $t_{p} / t_{w}$ increases the load distribution expands. The load distribution was then further simplified by representing it with an equivalent load block, which will give the same total force and

Figure 2.10 Column wall section positioned at the edges of the plate: Normal load distribution on the concrete surface ( $\sigma_{c}$ is $\sigma_{22}$ given Figure 2.8)

Figure 2.11 Column wall section positioned at the center of the plate: Normal load distribution on the concrete surface ( $\sigma_{c}$ is $\sigma_{22}$ given Figure 2.9)

Figure 2.12 Relationship between load block intensity factor $\sigma_{c} / \sigma_{w}$ and $t_{p} / t_{w}$
moment respect to the vertical axis. The relationship between the load block intensity factor $\sigma_{c} / \sigma_{w}$ and the $t_{p} / t_{w}$ can be plotted as in Fig. 2.12 with the following expression obtained for the case where the column wall section is positioned at the edges of the plate:

$$
\begin{equation*}
\frac{\sigma_{c}}{\sigma_{w}}=1.162-0.191 \frac{t_{p}}{t_{w}} \tag{2.9}
\end{equation*}
$$

and for when the column wall section is positioned at the center of the plate:

$$
\begin{equation*}
\frac{\sigma_{c}}{\sigma_{w}}=0.2584 \frac{t_{w}}{t_{p}} \tag{2.10}
\end{equation*}
$$

The width of the equivalent load block $t_{c}$ was found by imposing the condition that the total force of the equivalent load block is equal to the total force applied on the column wall.

$$
\begin{equation*}
\sigma_{c} t_{c}=\sigma_{w} t_{w} \tag{2.11}
\end{equation*}
$$

### 2.2.2 Normal Loads on the Boundary of Half-Space

Finite element studies of the base fixity problem, have shown that contact pressures between the base plate and concrete surface, are concentrated around the column wall section, rather than having a linear bending load distribution as assumed in Eq. (2.1). This is because the column wall thickness and base plate thickness in study are relatively thin, compared to the width or depth of the column. The distribution of the normal loads on the concrete surface depends on these thicknesses, and the location of the column wall section on the base plate. Once the normal load distribution on the concrete surface for a certain amount of bending moment is known, deformation can be obtained by solving the problem of normal loads on the boundary of the half-space, using solid mechanic approaches as suggested
in Sokolnikoff (1983). The column base rotation was found from the floor surface deformation, and then the base fixity was computed.

With the relationship between the load block intensity factor $\sigma_{c} / \sigma_{w}$ and $t_{p} / t_{w}$ known, different types of base plate configurations could then be studied. Four types of base plates were considered as shown in Fig. 2.13. The column load was assumed to be a combination of an axial and bending force. However, only the bending force contributes to the rotation of the base. The force in the column is transferred through the base plate and then onto the floor. The intensity of the normal load distribution was found by using either Eq. (2.9) or Eq. (2.10) depending on the location of the column wall section. The width of the load distribution was then found by using Eq. (2.11).

Type A has the base plate the same size as the column. Because all the column wall sections are located at the edges of the base plate, only Eq. (2.9) is needed to approximate the normal load distribution. Type B has the base plate extended out from the opening of the column, thus Eq. (2.10) must be used at the stiffeners. For type C the column is placed on a large base plate so only Eq. (2.10) is needed. For Type D the base plate is extended out from both sides of the flanges. For this base plate type Eq. (2.10) is used for the flanges and Eq. (2.9) is used at the web and stiffeners. Examples of the resulting normal load distribution for a 3 in . square C -section with $c=d / 2, t_{w}=t_{p}=0.10 \mathrm{in}$., for the different base plate types are shown in Fig. 2.14.

Once the load distribution on the concrete surface for a certain moment force is known, deformation of the concrete can be obtained by solving the problem of normal loads on the boundary of the half-space. Concrete surface deformation for the C-section example is shown in Fig. 2.14. The rotation was then found from the surface deformation, and the base fixity was calculated. A parametric study was carried out for a wide range of column base configurations to develop a new base fixity equation.

(b) Concrete surface deformation
(c)

Concrete surface deformation

(d)

Concrete surface deformation
Figure 2.14 (a) Base plate type A (b) Base plate type B (c) Base plate type C (d) Base plate type D

The parameters included are summarized in Table 2.1. Combinations of these parameters yielded a total of 500 models for each base plate type. Results for the different base plate types are shown in Figs. 2.15 through 2.18. It can be seen that the results of base plate type A are similar to type B while the results of base plate type C are similar to type D. This is mainly because the load at the stiffener and web is rather low. Most of the rotation takes place due to the loads from flanges.

New base fixity equations were obtained by fitting a regression line through the data results. For use with base plate type A or B , the equation is

$$
\begin{equation*}
\frac{M}{\theta}=\frac{7}{25} b d^{2} E_{c} \tag{2.12}
\end{equation*}
$$

For use with base plate type C or D , the equation is

$$
\begin{equation*}
\frac{M}{\theta}=\frac{9}{25} b d^{2} E_{c} \tag{2.13}
\end{equation*}
$$

For practical purposes it is recommended that a single base fixity equation, Eq. (2.12), be used for all types of base plates. As can be seen Figs. 2.17 and 2.18, the design will simply be slightly more conservative when Eq. (2.12) is used for base plate type C or D. The stiffness of the equivalent floor beam corresponding to Eq. (2.12) for rack not braced against sidesway is

$$
\begin{equation*}
\frac{I_{f}}{L_{f}}=\frac{7}{3000} b d^{2} \tag{2.14}
\end{equation*}
$$

for rack braced against sidesway is

$$
\begin{equation*}
\frac{I_{f}}{L_{f}}=\frac{7}{1000} b d^{2} \tag{2.15}
\end{equation*}
$$

The base fixity equations presented here are suggested only for the initial stiffness of the connection, namely, only the first stage of the behavior as defined by

Table 2.1 Column and Base Plate Dimensions in Study

Figure 2.15 Base fixity results for base plate type A

Figure 2.16 Base fixity results for base plate type B

Figure 2.17 Base fixity results for base plate type C

Figure 2.18 Base fixity results for base plate type D

Salmon, Schenker and Johnston (1955) where the base plate is still in full contact with the concrete surface, having trapezoidal compression stress distribution. By considering the axial force $P$ and bending moment $M$, to prevent tension stresses from occurring on the concrete surface, an upper bound limit of the equations can be found as

$$
\begin{equation*}
\frac{M}{P} \leq \frac{S}{A} \tag{2.16}
\end{equation*}
$$

This upper bound limit when used for columns with thick base plates as shown in Fig 2.19a, the contact stress area $A$, would be equal to $b d$, and $S$ the elastic section modulus of the rectangular area about the axis of bending wound equal to $b d^{2} / 6$, therefore Eq. (2.16) becomes

$$
\begin{equation*}
\frac{M}{P} \leq \frac{d}{6} \tag{2.17}
\end{equation*}
$$

However, when used for design columns with thin base plates as shown in Fig 2.19b, $A$ would instead equal to $2 t(d+b)$, where $t$ is the thickness of the contact area, and $S$ would be equal to $\operatorname{td}(d / 3+b)$, therefore in this case Eq. (2.16) becomes

$$
\begin{equation*}
\frac{M}{P} \leq \frac{d(d+3 b)}{6(d+b)} \tag{2.18}
\end{equation*}
$$

For practical purposes it is recommended that a single upper bound limit, Eq. (2.17), should be used for all types of base plate because it is always more conservative than using Eq. (2.18).

Once the upper bound limitation has been reached, the stiffness of the connection is expected to decrease. The RMI specification does not explicitly give an upper bound limit for its base fixity equation but expects that the limit will not be reached for gravity load design.

Figure 2.19 (a) Thick base plate (b) Thin base plate

### 2.2.3 Base Fixity Charts

The proposed base fixity equation provides a rough estimate of the connection stiffness approximated from a wide range of column base configurations. To obtain a more accurate value for a particular column base, charts given in Appendix B should be used. The charts were developed by using the data points given in Figs. 2.15 through 2.18 , then rearranged and curved to fit them such that the data could be read directly from these charts. The charts are given for all base plate types with box column sections. Two column wall thicknesses were provided, $t_{w}=0.05 \mathrm{in}$. and $t_{w}=0.10 \mathrm{in}$. with the column dimension ranging from a square section to a 2 by 1 rectangular section. In all cases there are a group of five solid lines where the top line refers to base plate thickness of $t_{p}=3 t_{w}$, the second line $t_{p}=2.5 t_{w}$, the third line $t_{p}=2 t_{w}$, the fourth line $t_{p}=1.5 t_{w}$, and the bottom line $t_{p}=t_{w}$.

The base fixity values given here assume the column and base plate material to be $E_{s}=29500 \mathrm{ksi}$ and $v=0.3$ while for the concrete floor $E_{c}=2950 \mathrm{ksi}$ and $v=0.2$. For other concrete material properties, assuming that Eq. (2.9) and Eq. (2.10) still hold, the base fixity can be found by modifying the obtained chart value as follows:

$$
\begin{equation*}
\frac{M}{\theta}=\frac{G}{G_{\text {chart }}}\left(\frac{M}{\theta}\right)_{\text {chart }} \tag{2.19}
\end{equation*}
$$

where $G_{\text {chart }}$ is equal to 1229 ksi , and $G$ is the shear modulus of elasticity of the concrete material of interest.

### 2.3 FINITE ELEMENT ANALYSIS VERIFICATION

Non-linear finite element analyses of the column to floor connection were performed using $A B A Q U S$ in order to verify the proposed base fixity equation. The geometry and boundary condition of the finite element model were made to best simulate the A-LDR column with base plate type $B$ connection (columns 3CS1.625x90). The finite element model of the column base is shown in Fig. 2.20.

Finite element assumptions are as follows: The vertical and lateral loads transferred from the frame to the isolated column were modeled by nodal forces applied at the centroid of the column on the top plate as shown in Fig. 2.20. The ratio of the lateral load with respect to the vertical load is maintained at 0.015 throughout the analysis. The top plate has been thickened to avoid large deformation and localized failure due to the concentrated loads, and lateral bracing is also provided at the top plate to prevent the column from twisting. In addition, because only one anchorage bolt on the left was chosen for this model, it was expected that the placement of the bolts would affect the behavior of the column. Therefore, both directions of the lateral load were considered. Positive and negative signs of the direction are given in Fig. 2.20. An idealization of the boundary conditions of the anchorage bolts connection was made by the matching displacements of the base plate nodes and the concrete nodes.

The four node general purpose shell element was used to model the column and base plate while an eight node brick element was used to model the concrete floor. Contact surfaces were defined between the base plate and the concrete to simulate their interaction. No friction was considered between the two surfaces. In addition, since the floor was assumed to be a half-space, eight node infinite elements were used to model the far-field region. The material model used for the column and base plate was elastic-plastic with strain hardening $F_{y}=45 \mathrm{ksi}, F_{u}=59 \mathrm{ksi}, E=29500 \mathrm{ksi}$,

Figure 2.20 Column base finite element model

Figure 2.21 Column base finite element analysis results (a) von Mises Stress (b) Normal stress, $\sigma_{22}$ on the concrete surface

Figure 2.22 Column base finite element analysis verification
$E_{s t}=E / 45, v=0.3$, and $e_{s t}$ was 15 times the maximum elastic strain, while the concrete was assumed elastic with $E_{c}=2950 \mathrm{ksi}$ and $v=0.2$. Using these finite element modeling assumptions a parametric study was carried out by varying $t_{p} / t_{w}$ from 1 to 3 . Deformation and stress distribution resulted from the finite element analysis for the case of loading in the positive direction is as shown in Fig. 2.21. The rotation of the base plate was obtained and plotted against the applied moment to compare with the RMI and the proposed base fixity equation as shown in Fig. 2.22. As can be seen in this figure the proposed equation agrees better with the finite element results than the RMI equation does.

### 2.4 CONCLUSIONS

It was shown in this chapter that the current RMI base fixity equation underestimates the stiffness. Several analytical models of the column base were studied. The base fixity was found by solving a normal load on the boundary of the half-space problem. With this approach a parametric study was carried out for a wide range of base configurations to develop a new base fixity equation. Unless actual tests are conducted to obtain the base fixity, the proposed base fixity equation, Eq. (2.12), along with the upper bound limits, Eq. (2.17), of the base fixity behavior should be used. Finite element studies were used to verify the proposed equation. The proposed equation agrees well with the finite element solution. Some errors do occur from the assumptions in the approach, such as neglecting the flexibility of the base plate and using an approximate load block for the load distribution on the concrete surface.

# Chapter 

## Beam to Column Connections

### 3.1 INTRODUCTION

In storage racks, beam end connectors are used to make beam to column connections. The semi-rigid nature of this connection is primarily due to the distortion of the column walls, tearing of the column perforation, and distortion of the beam end connector. The storage rack stability depends significantly on the behavior of this connection, thus it is important to have the means for predicting it. Designs of these connections vary widely; making it is impossible to develop a general analytic model. Instead, beam to column connection tests are usually done to determine the relationship of the moment at the joint $M$ and the change in angle between the column and the connecting beam $\theta$.

### 3.2 BEAM TO COLUMN CONNECTION TESTS

The RMI specification recommends the use of a cantilever test or a portal test. Schematics of these test setups are shown in Figs. 3.1 and 3.2. The result from the cantilever test is normally used to design beams and connections; while the result from the portal test is used as connection stiffness in sidesway analyses. The following is a review of these tests. In the cantilever test the constant connection stiffness $F$ relating the moment to the rotation as

$$
\begin{equation*}
F=\frac{M}{\theta} \tag{3.1}
\end{equation*}
$$

is determined by using the known applied vertical load $P$ and deflection of the free end of the cantilever $\delta$ in the following expression

$$
\begin{equation*}
\delta=P L_{b}^{2}\left(\frac{L_{c}}{16 E I_{c}}+\frac{L_{b}}{3 E I_{b}}+\frac{1}{F}\right) \tag{3.2}
\end{equation*}
$$

where $E$ is the modulus of elasticity, $L_{b}$ and $L_{c}$ are the length of the beam and column segment, $I_{b}$ and $I_{c}$ are the moments of inertia of the beam and column segment, respectively. Solving Eq. (3.2) for $F$, the following is obtained:

$$
\begin{equation*}
F=\frac{1}{\frac{\delta}{P L_{b}^{2}}-\frac{L_{c}}{16 E I_{c}}-\frac{L_{b}}{3 E I_{b}}} \tag{3.3}
\end{equation*}
$$

With $M=P L_{b}$ and $F$ known, $\theta$ can then be determined from Eq. (3.1) for each load step. Plots such as Fig. 3.3 giving the moment and rotation relationship may then be developed. Instantaneous stiffness $\Delta F$ can be found by connecting the resulting data points or by substituting $\Delta P$ for $P$, and $\Delta \delta$ for $\delta$ into Eq. (3.3) where $\Delta P$ is the load increment, and $\Delta \delta$ is the deflection increment due to $\Delta P$. The RMI specification recommends that the connection stiffness to be used in linear analyses can be given as

Figure 3.1 Cantilever test

Figure 3.2 Portal test

Figure 3.3 Beam to column connection stiffness
the $F$ determined from Eq. (3.3) with $P$ equal to 0.85 times the ultimate load and $\delta$ equal to the deflection at that load.

In the portal test, a certain amount of vertical load is applied before the connection stiffness is determined. By applying an additional horizontal load and measuring the corresponding lateral deflection, $F$ can be computed from the following expression:

$$
\begin{equation*}
\delta=\frac{H h^{2}}{2}\left(\frac{h}{3 E I_{c}}+\frac{L}{6 E I_{b}}+\frac{1}{F}\right) \tag{3.4}
\end{equation*}
$$

where $H$ is the horizontal load per beam. Two beams are required in this test assembly; therefore, a horizontal load of $2 H$ is applied in the test, $\delta$ is the lateral deflection corresponding to a horizontal load of $2 H, h$ is the distance from the floor to top of the beam, and $L$ is the distance between the centroid of the two columns parallel with the shelf beam. Solving Eq. (3.4) for $F$, the following is obtained:

$$
\begin{equation*}
F=\frac{1}{\frac{2 \delta}{H h^{2}}-\frac{h}{3 E I_{c}}-\frac{L}{6 E I_{b}}} \tag{3.5}
\end{equation*}
$$

The RMI specification recommends that $F$ determined from Eq. (3.5) be used as the connection stiffness in sidesways analyses. Tests for $F$ with vertical loads at both the design load and the ultimate load levels should be conducted since the behavior at both of these loads are of interest.

If the vertical load is applied such that it is equally distributed over the entire bay then the vertical force on each shelf beam can be assumed to be a uniform distribution load $w$, (force per length). The pre-existing moments in the joints due to this load, before the horizontal load is applied can be determined as follows:

$$
\begin{equation*}
M=\frac{w L^{3}}{24 E I_{b}\left(\frac{h}{3 E I_{c}}+\frac{L}{2 E I_{b}}+\frac{1}{F}\right)} \tag{3.6}
\end{equation*}
$$

As the horizontal load is applied to the right as in Fig. 3.2, the left joint will loosen and the right joint will tighten up, meaning the pre-existing moment in the joints from Eq. (3.6) will decrease by $H h / 2$ in the left joint and increase by $H h / 2$ in the right joint. This, however, assumes that both joints have the same stiffness, but generally this may not be the case, for example if the pre-existing moment in the joints is equal to $M_{n}$ as shown in Fig. 3.3. As the horizontal load is applied, the stiffness of the left and right joints will instead be approximately $\Delta F_{n}$ and $\Delta F_{n+1}$, respectively. The lateral displacement in this case can be found as:

$$
\begin{equation*}
\delta=\frac{H h^{2}}{2}\left[\frac{\left(\frac{h}{3 \mathrm{EI}_{c}}+\frac{L}{2 \mathrm{EI}_{b}}+\frac{1}{\Delta F_{n}}\right)\left(\frac{h}{3 \mathrm{EI}_{c}}+\frac{L}{2 \mathrm{EI}_{b}}+\frac{1}{\Delta F_{n+1}}\right)}{\left(\frac{h}{3 \mathrm{EI}_{c}}+\frac{L}{2 \mathrm{EI}_{b}}+\frac{\Delta F_{n}+\Delta F_{n+1}}{2 \Delta F_{n} \Delta F_{n+1}}\right)}-\frac{L}{3 \mathrm{EI}_{b}}\right] \tag{3.7}
\end{equation*}
$$

By equating Eq. (3.4) and Eq. (3.7) it can be found that the constant connection stiffness determined from Eq. (3.5) is actually a combination of these different joint stiffnesses $\Delta F_{n}$ and $\Delta F_{n+1}$ as follows:

$$
\begin{equation*}
F=\frac{\Delta F_{n}+\Delta F_{n+1}+2 \Delta F_{n} \Delta F_{n+1}\left(\frac{h}{3 E I_{c}}+\frac{L}{2 E I_{b}}\right)}{2+\left(\Delta F_{n}+\Delta F_{n+1}\right)\left(\frac{h}{3 E I_{c}}+\frac{L}{2 E I_{b}}\right)} \tag{3.8}
\end{equation*}
$$

The connection stiffness of the individual joints is not obtained from the portal test but is instead an approximate average value of the connection stiffness as the tightening up and the loosening process is obtained. The loosening process may not be as simple as assumed in the above example where the unloading stiffness is same as the loading stiffness $\Delta F_{n}$. If the connections were loaded beyond the elastic range, permanent
deformation would occur in the joint, resulting in different moment and rotation relationships in the loading and unloading process.

### 3.3 PROPOSED PORTAL TEST

An alternative beam to column test presented here is to be used instead of the cantilever test. In the cantilever test the shear to moment ratio of the actual frames may not be well represented. For some connections the behavior may depend significantly on this ratio. Namely, if the cantilever test is conducted for different $L_{b}$ values, the moment and rotation relationships obtained from each of these tests will be different. To solve this problem, a proposed connection test where the entire bay is assembled the same as in the portal test is to be used. This proposed procedure shown in Fig. 3.4 will be referred to in this study as the proposed portal test. This test is similar to the previous portal test but instead of applying the horizontal loads, vertical loads are applied incrementally and the corresponding mid-span beam deflection $\delta$ is measured. The vertical load applied must be equally distributed over the entire bay so that the vertical force on each shelf beam can be assumed to be a uniformly distribution load $w$. The developing moment in each joint will be the same in this test and the expression for the maximum beam deflection at mid-span can be found as follows:

$$
\begin{equation*}
\delta=\frac{w L^{4}}{384 E I_{b}}\left[5-\frac{4}{1+\frac{2 E I_{b}}{L}\left(\frac{h}{3 E I_{c}}+\frac{1}{F}\right)}\right]+\frac{w L h}{2 A E} \tag{3.9}
\end{equation*}
$$

Figure 3.4 Proposed portal test

Solving Eq. (3.9) for $F$, the following is obtained:

$$
\begin{equation*}
F=\frac{1}{\frac{L}{2 E I_{b}}\left(\frac{4 w L^{4}}{5 w L^{4}-384 E I_{b}\left(\delta-\frac{w L h}{2 A E}\right)}-1\right)-\frac{h}{3 E I_{c}}} \tag{3.10}
\end{equation*}
$$

with $M$ the same as given in Eq. (3.6) and $F$ known, $\theta$ can then be determined from Eq. (3.1) for each vertical load step. Plots such as in Fig. 3.3 giving the moment and rotation relationship may then be developed. The load carrying capacity of the entire bay may also be determined from this test whether failure is due to the connection or the shelf beam. However, if the load carrying capacity is not of interest, the proposed portal test could be conducted prior to the portal test. The mid-span deflection $\delta$ could be measured in the vertical loading process. The connection stiffness from the proposed portal test can then be used in designing beams while the connection stiffness from the portal test can be used in sidesway analyses.

### 3.4 FINITE ELEMENT SIMULATION OF THE CANTILEVER TEST

A cantilever test of a light duty rack connection was conduced by Peköz (1975). The vertical load was applied by a jack until failure took place at the connection. Results showed that the failure took place with tearing of the column perforation by the upper hex stud. The load-deflection relationship and the determination of the moment-rotation relationship from the test results are summarized in Table 3.1. A finite element simulation of this test is presented in this study. The objective is to develop a finite element model that best represents the behavior of the connection so that the modeling assumptions can later be implemented into the beam to column connections in the frame analysis study in Chapter 5.

In order to study the behavior of the connection, nonlinear finite element analyses were performed using ABAQUS. The geometry, boundary and loading conditions of the finite element model were made to best simulate the cantilever test as shown in Fig. 3.5. A 30 in . length column was fixed in all degrees of freedom at both ends to represent the ends of the column that were welded to immovable supports. A 26 in . beam with an end plate was connected at mid height of the column. Contact surfaces were defined between the end plate and the column to simulate their interaction as shown in Fig. 3.6. The lower hex stud was modeled by the use of multipoint constraints to provide a pinned joint between the node on the end plate and the column, while the upper hex stud was modeled by the use of multipoint constraints and non-linear axial springs as shown in Fig. 3.7. The non-linear axial spring was used to capture the initial looseness behavior of the joint. The stiffness of the spring was calibrated to best match initial looseness behavior of the test result.

The concentrated load was applied 24 in . from the connection to simulate the jack load. The material model used was elastic-plastic with strain hardening $F_{y}=45 \mathrm{ksi}, F_{u}=59 \mathrm{ksi}, E=29500 \mathrm{ksi}, E_{s t}=E / 45, v=0.3$, and $e_{s t}$ was 15 times the maximum elastic strain. Failure mode at ultimate load is shown in Fig. 3.8. The connection rotation was determined by monitoring node $P_{3}$ and $P_{4}$ as shown in Fig. 3.9 to find the angle of rotation of the beam and node $P_{1}$ and $P_{2}$ to find the movement of the column to correct the connection rotation. A moment-rotation curve resulting from the finite element simulation and the physical test are compared in Fig. 3.10. The beam to column stiffness obtained from $85 \%$ of the joint moment capacity as suggested by the RMI specification used in linear frame analyses was also plotted for comparison.

### 3.5 CONCLUSIONS

A new beam to column connection test to be used instead of the cantilever test has been presented in this study. The shear to moment ratio in an actual frame is better represented by this proposed portal test than the cantilever test. For some designs, the connection behavior may depend significantly on this ratio. Therefore it is recommended that in addition to current beam to column connection tests, this proposed portal test should be included as a possible means of determining the moment to rotation relationship of the connection.

The beam to column connection stiffness obtained from the finite element cantilever test simulation agrees well with the test results. However, the finite element model was not able to capture the failure mode which was observed in the test. In the test the failure took place with tearing of the column perforation by the upper hex stud. Thus the connection ultimate moment capacity obtained from the finite element model was higher than obtained from the test. Improvement in the finite element result can be made with better modeling details of the connection stud and considering fracture mechanics.

### 4.1 INTRODUCTION

The current RMI design provision for cold-formed steel members is similar to the AISI specification. Both specifications consist of the following general steps. First, the overall stability of the member is considered. Once the overall buckling stress is known, then the design equations are used to determine the nominal failure stress, whether the member will fail from elastic buckling, inelastic buckling, or yielding. With the nominal failure stress known, the corresponding effective section properties can then be computed. Effective section properties are used to account for the local buckling of thin-walled sections. The nominal member strength is determined based on the governing nominal failure stress and the effective section properties. Finally, the design member strength is obtained by multiplying the nominal member strength by a resistance factor in the case of LRFD or dividing it by a safety factor in the case of ASD. However, special considerations must be given to members subject to a combined compressive axial load and bending. Additional steps must also be taken to account for various possible modes of failure and the presence of second-
order moments. Based on the general design steps discussed above, studies were carried out in this chapter to verify or modify the current design provisions for member design.

### 4.2 ELASTIC BUCKLING STRENGTH OF PERFORATED MEMBERS

The column sections in storage racks are perforated for the purpose of easy assembly of the beam end connector. It is well known that the presence of such perforation reduces the local buckling strength of the individual component element and the overall buckling strength of the section. The significance of this reduction will however depend on the geometry and material properties of the member and the boundary conditions. The RMI specification currently allows the use of unperforated section properties to predict the overall elastic buckling strength of perforated members, thus assuming that the presence of such perforation does not have significant influence on the reduction of the overall elastic buckling strength. The objective of this study is to check this assumption. Two finite element buckling analyses studies were carried out to investigate how the perforations affect the local and overall buckling strength.

The first study considered a rectangular plate with two rows of perforations as shown in Fig. 4.1. The plate was modeled to represent the web of a Section A-LDR shown in Fig. 4.2a. The actual holes in the web are irregular shapes. Here they are simplified by an approximate equivalent rectangular hole. The plate is subject to a uniform compression stress in the longitudinal direction. Two boundary condition cases were considered as shown in Fig. 4.1. The actual boundary condition along the longitudinal edges lies between these two extreme cases because the web to flange junction provides some rotational stiffness. The elastic critical buckling stress was

(a)

(b)

Figure 4.1 Perforated plate buckling modes (a) Case I (b) Case II

Table 4.1 Values of Plate Buckling Coefficients

solved by using the computer program CU-PBF shown in Appendix H. The program uses the finite element method with four-node rectangular thin plate elements to solve this eigenvalue problem. With the critical buckling stress known, the plate-buckling coefficient $k$ was calculated and then compared with the unperforated long plate values given by the AISI specification. Table 4.1 summarizes the results. Results show that the presence of such perforations significantly reduces the $k$ value in both cases.

The second study was carried out to compare the buckling strengths of perforated and unperforated sections. Three C-sections were considered: A-LDR, A-LDR-2, and A-HDR. Their cross sectional geometry is given in Fig. 4.2 and section properties are summarized in Tables 4.2, 4.3, and 4.4. The cross sectional geometry of Sections A-LDR and A-LDR-2 are similar but their section thicknesses are different. The elements of Section A-LDR are thick making it locally stable, while the elements of Section A-LDR-2 are thin making it locally unstable under uniform compressive yield stress. All three sections were studied as both a concentrically loaded compression member and a flexural member subject to bending about the strong axis. Boundary conditions at the ends of the member for both cases were pined condition such that the effective length for flexural buckling of both the strong and weak axis and torsion were equal to the length of the member. The critical buckling load was found for different length members. Two approaches were used to solve the buckling problem and then compared: the first approach is using finite element method using the ABAQUS computer program where the four node general purpose shell element was used to model the member, and second approach is using the theoretical overall buckling equations as given in the AISI specification. The theoretical overall buckling equations were solved for arbitrary open thin-walled sections by using the computer program CU-TWP shown in Appendix H. The finite element method is considered to give more accurate results.

Table 4.2 Section A-LDR Dimensions and Properties

Table 4.3 Section A-LDR-2 Dimensions and Properties

Table 4.4 Section A-HDR Dimensions and Properties

Finite element models range from a member length of 12 to 120 in . with a 6 in. increment between models. The theoretical values were obtained for the unperforated section, weighted section, average section, and in addition the net moment of inertia section for the flexural buckling mode. A weighted section as shown in Tables 4.2, 4.3, and 4.4 , refers to a section that uses an average thickness in the perforated segment of the section to account for the absence of the material from the holes along the length of the section. An average section as also shown in Tables 4.2, 4.3, and 4.4, refers to a section that uses a uniform average thickness to account for the absence of the material from the holes in the section. The material volume of the weighted section and the average section is the same, and is equal to the perforated section. The cross sectional area of a weighted section is the same as an average section despite the fact that the weighted section has varying element thicknesses while the average section does not. The different possible overall buckling modes of these open thin-walled sections involve torsional-flexural buckling and flexural buckling for the concentrically loaded compression member, and lateral buckling for the flexural member as shown in Figs. 4.3 and 4.4.

The results are given in Figs. 4.5 and 4.6 for Section A-LDR, Figs. 4.7 and 4.8 for Section A-LDR-2, and Figs. 4.9 and 4.10 for Section A-HDR. The vertical axes in the figures are the elastic axial buckling load $P_{e}$ divided by the axial load causing the yield of the full unreduced gross section $P_{y}=A F_{y}$, and the elastic flexural buckling moment $M_{e}$ divided by the moment causing initial yield at the extreme compression fiber of the full unreduced gross section $M_{y}=S_{f} F_{y}$.

Results indicated that increasing the presence of perforations in the section will reduce the buckling strength. To take this into account, instead of using the unperforated section properties to predict the buckling strength of perforated sections, as assumed in the current design specification, better results can be obtained by using

the weighted section, or the average section properties for torsional-flexural buckling, the average section properties for lateral buckling, and the net moment of inertia section properties for flexural buckling. The torsional-flexural buckling could be computed either by using the weighted section or the average section because their results are almost the same. It is however more convenient to use the average section because its section properties are easier to compute.

The critical modes of the finite element models are summarized in Tables 4.5 and 4.6. It should be noted, however, that although some of the models are indicated as having instability by the torsional-flexural buckling or lateral buckling it is possible that the buckling strength may be much lower than the theoretical values. This is because they are still in transition, switching between the different buckling modes, thus the cross section deforms as a combination of distortional and torsional-flexural buckling or distortional and lateral buckling, which contradicts the theoretical buckling equations that assume that the cross section does not deform.

### 4.3 TORSIONAL-FLEXURAL BUCKLING

Torsional-flexural buckling is usually the governing critical buckling mode for columns having an open-cross section. Generally the torsional-flexural buckling equation of the AISI specification is used to determine the buckling load. This equation, however, imposes several boundary condition assumptions, which often do not represent the actual bracings of the member, making the buckling load prediction sometimes inaccurate. Finite element buckling analysis studies were carried out to evaluate this equation. An open-section 3-node quadratic beam element was used to solve the problem in study. Open-section beam elements have a warping magnitude as an additional degree of freedom at each node. Five studies were carried
out, all of which used the Column Section-C1 shown in Table 4.7, and local axis definitions as shown in Table 4.8.

Study I: is a convergence study for a simply supported torsional-flexural buckling problem. As shown in Fig. 4.11 using 2 elements is sufficient to solve this problem. In the following studies, where additional interior braces are given; 30 elements were used to ensure the accuracy of the result.

Study II: is a torsional-flexural buckling problem of a simply supported column with two additional interior braces that constrain the column from twisting as shown in Fig. 4.12. The buckling load was obtained from the finite element analysis and compared to those values calculated from the buckling equation. To use the torsional-flexural buckling equation $K_{x} L_{x}$ and $K_{t} L_{t}$ must be known. In this study $K_{x} L_{x}$ is 60 in . and $K_{t} L_{t}$ was determined using two different approaches, for which their results are also compared in this study. The first approach, which is commonly used in current practice, was to assume the effective length factor $K_{t}$ for torsional buckling to be 0.8 , and the unbraced length against twisting $L_{t}$ to be the maximum distance between adjacent braces. The second approach, which is considered to give a more accurate result than the first approach, was to determine $K_{t} L_{t}$ from a torsional buckling analysis. Torsional buckling or flexural buckling analyses were performed by constraining certain degrees of freedom of the member as given in Table 4.8. As seen in Fig. 4.12 and Table 4.9 the torsional-flexural buckling equation can become quite conservative, in some cases over 25 percent.

Study III: is similar to Study II but with only one interior brace. The results shown in Fig 4.13 and Table 4.10 again suggest that the torsional-flexural buckling equation is conservative.

Study IV: shown in Table 4.11 looks at the torsional-flexural buckling problem for certain effective lengths $K_{x} L_{x}$ and $K_{t} L_{t}$. For example when the torsional-

flexural buckling equation is used, the results are obviously $\mathrm{A}=\mathrm{B}=\mathrm{C}$, $\mathrm{D}=\mathrm{E}=\mathrm{F}=\mathrm{G}$, and $\mathrm{H}=\mathrm{I}$, but finite element results suggested that $\mathrm{A}=\mathrm{B}=\mathrm{C}$, $\mathrm{D}=\mathrm{E} \neq \mathrm{F} \neq \mathrm{G}$, and $\mathrm{H} \neq \mathrm{I}$. The buckling load determined from the AISI equation for cases F, G, H, and I is conservative compared with finite element results.

Study V: shown in Table 4.12 looks at the torsional-flexural buckling problem for different combinations of the effective lengths $K_{x} L_{x}$ and $K_{t} L_{t}$, to represent pallet rack bottom story columns. In this study $K_{t} L_{t}$ was determined from a torsional buckling analysis. For example, case E has the column base, and at elevations 12 and 60 in., constrained against twisting. Combinations such as $\mathrm{I}+\mathrm{E}, \mathrm{II}+\mathrm{E}$, or III +E may represent the columns of a sidesway uninhibited frame. In these cases, the torsionalflexural buckling equation is over 20 percent conservative compared with the finite element results.

Studies II through V have shown that the buckling load obtained from using the AISI torsional-flexural buckling equation can be quite conservative compared to the finite element solution. There are two particular reasons for this. First, the buckling equation assumes that the buckled shape maximum deflection and maximum rotation coincide; however, depending on the boundary conditions of the member this may not always be the case. Second, the buckling equation assumes that the translation support, $u_{y}=0$, is about the shear center but the finite element analysis boundary conditions are imposed at the cross-section centroid. The AISI torsional-flexural buckling equation has proved to be a source of the conservatism in the current design provisions.

### 4.4 EFFECTIVE LENGTHS

The AISI, AISC and RMI specifications use the effective length approach for assessing frame stability. The approach relies significantly on the prediction of the effective lengths and critical buckling load of the member. For pallet racks, the value of $K_{x}$ for column flexural buckling in the direction perpendicular to the upright frames is usually determined from the alignment charts, elastic buckling analysis, or simply assumed to be 1.7 as suggested by the RMI specification. The RMI specification also recommends that $K_{y}$ for column flexural buckling in the plane of the upright frame can be taken as one, and $K_{t}$ for column torsional buckling can be taken as 0.8 , providing that the upright frame has adequate braces. These recommended $K$ values, are approximated from numerous typical rack assemblies. Structural frame elastic buckling analysis is needed if the exact $K$ values are to be computed. The objective of this study was to evaluate the RMI recommended values of $K_{y}$ and $K_{t}$ for column buckling.

Finite element elastic buckling analyses of upright frames were performed to obtain $K_{y}$ and $K_{t}$ for column buckling, and evaluate the AISI torsional-flexural buckling equation. A parametric study was carried out for different types of upright frame configurations. The parameters included: two load cases as shown in Fig. 4.14, two types of column sections as shown in Table 4.7, two types of braces also shown in Table 4.7, and six types of bracing patterns as shown in Tables 4.13 through 4.15. The finite element assumptions were as follows: The joint connection between the braces and columns were considered to be continuous except for the warping degree of freedom. The warping degree of freedom was constrained only at the ends of the braces. Column base fixity for both the strong and weak axis bending of the column was modeled by torsional springs with the stiffnesses determined from the proposed

base fixity equation given in Chapter 2. In addition to the torsional springs, the column bases were also constrained against twisting.

The $K_{y}$ and $K_{t}$ values for columns was determined from flexural buckling and torsional buckling analyses of the upright frame. To perform these analyses without having torsional-flexural buckling certain degrees of freedom of the columns had to be constrained as shown in Table 4.8. The obtained $K_{y}$ and $K_{t}$ values are given in Tables 4.13 through 4.15 for the different upright frame configurations, and an example of the buckling mode shapes are shown in Fig. 4.15. From these tables it was found that, the RMI recommendation of $K_{y}$ taken as one is conservative with the exception of upright frame type F. Upright frame type F has inadequate braces causing the upright frame to be in sidesway buckling mode. It was also found that the recommendation of $K_{t}$ taken as 0.8 is in most cases reasonable. Upright frame type E had the load applied between the bracings making the calculation of $K_{t}$ very conservative. In this study it was found that it is very important to constrain the column bases from twisting, otherwise $K_{t}$ can be more than one. Generally this assumption should be valid because the base plate usually has at least one anchorage bolt, and the friction between the steel base plate and concrete floor should be sufficient to prevent the bases from twisting. The ideal column bases condition to prevent it from twisting is however to have more then one anchorage bolt.

In the following study $K_{x}$ for columns was assumed to be 1.2. A certain $K_{x}$ value can be defined by providing torsional springs as shown in the Fig. 4.14 to resist the columns from flexural buckling in the direction perpendicular to the upright frame. Elastic buckling analysis of the upright frames was performed to determine the critical buckling load, $P_{e}$. Summaries of the results are given in Tables 4.16 and 4.17. Upright frame type A through E has torsional-flexural as the column critical buckling mode while upright frame type F has flexural buckling about the weak axis.

Calculation of the torsional-flexural buckling load $P_{\text {cal }}$ by using the buckling equation with $K_{t}$ from Tables 4.13 through 4.15, and $K_{x}$ from Tables 4.16 and 4.17 was carried out. And calculation of the torsional-flexural buckling load $P_{R M I}$ by using the buckling equation with $K_{t}=0.8$, and $K_{x}$ from Tables 4.16 and 4.17 was also carried out. As shown in Tables 4.16 and 4.17 the torsional-flexural buckling values calculated from the AISI torsional-flexural buckling equation in all cases are conservative compared with the finite element results.

### 4.5 EFFECTIVE DESIGN AREA

The effective design width equations of the AISI specifications are not applicable for designing rack columns, because of the presence of perforations. Stub-column tests are instead required in the RMI specification to account for the member local behavior. By measuring the axial load and the corresponding axial shortening in the stub-column test, the relationship between the stress on the effective section $F_{n}$ and the effective area $A_{e}$ can be obtained; however, for tests where only the ultimate strength of the stub-column is measured, the following effective design area equation of the RMI specification must be used

$$
\begin{equation*}
\frac{A_{e}}{A_{\text {net min }}}=1-(1-Q)\left(\frac{F_{n}}{F_{y}}\right)^{Q} \tag{4.1}
\end{equation*}
$$

where

$$
Q=\frac{\text { ultimate strength of stub-column }}{F_{y} A_{\text {net min }}}
$$

The following studies were carried out to verify or modify this effective design area equation.

### 4.5.1 Stiffened elements

In order to evaluate the effective design area equation, finite element simulations of stub-column tests were carried out to obtain the relationship between $F_{n}$ and $A_{e}$. This was then compared to those relationships between $F_{n}$ and $A_{e}$ suggested by Eq. (4.1). However, before this study was carried out, finite element modeling assumptions, in particularly the initial geometric imperfection assumption, had to first be verified.

Precise data of the distribution on the initial geometric imperfection was not available. Imperfection was therefore introduced by using the critical buckling mode shape obtained from buckling analysis. Finite element studies of a simply supported rectangular plate under uniform compression displacement as shown in Fig. 4.16 has shown that when the maximum magnitude of imperfection $\delta$ is assumed equal to one tenth of the element thickness, the analytical results tend to agree with the well known effective design width equation

$$
\begin{equation*}
\rho=(1-0.22 / \lambda) / \lambda \text { for } \lambda>0.673 \text { otherwise } \rho=1 \tag{4.2}
\end{equation*}
$$

This initial geometric imperfection assumption seems reasonable and therefore was used in subsequent finite element studies. The material model used in the above finite element study was elastic-plastic with strain hardening $F_{y}=55 \mathrm{ksi}, F_{u}=70 \mathrm{ksi}$, $E=29500 \mathrm{ksi}, E_{s t}=E / 45, v=0.3$, and $e_{s t}$ is 15 times the maximum elastic strain.

Similar to the stub-column test, by measuring the axial load and the corresponding axial shortening of the stiffened element, the relationship between $F_{n}$ and $A_{e}$ was obtained. With these values known the relationship between $P_{n} / P_{y}$ and $F_{n} / F_{y}$ could be found. In Fig. 4.17, the analytical results are compared to the following equation

Figure 4.16 Effect of initial geometric imperfection on effective design width

Figure 4.17 Stiffened compression elements - Correlation between effective design width equation and analytical results

Figure 4.18 Stiffened compression elements - Correlation between RMI effective design area equation and analytical results

Figure 4.19 Stiffened compression elements - Correlation between proposed effective design area equation and analytical results

$$
\begin{equation*}
\frac{P_{n}}{P_{y}}=\rho \frac{F_{n}}{F_{y}} \tag{4.3}
\end{equation*}
$$

where $\rho$ is computed according to Eq. (4.2). As can be seen in Fig. 4.17, at the ultimate load ( $P_{n}$ when $F_{n}=F_{y}$ ) the analytical results agree well with the effective design width equation because of the initial geometric imperfection calibration. However it was found that at design loads ( $P_{n}$ when $F_{n}<F_{y}$ ) the effective design width equation is quite conservative compared to the analytical solution. In Fig. 4.18, the analytical results are compared to the following equation

$$
\begin{equation*}
\frac{P_{n}}{P_{y}}=\frac{F_{n}}{F_{y}}\left(1-(1-Q)\left(\frac{F_{n}}{F_{y}}\right)^{Q}\right) \tag{4.4}
\end{equation*}
$$

which is the RMI effective design area equation Eq. (4.1) multiplied by $F_{n} / F_{y}$ to give the relationship between $P_{n} / P_{y}$ and $F_{n} / F_{y}$. The $Q$ factor is obtained from the finite element solution; therefore, analytical results and Eq. (4.4) match at the ultimate load. It was found that at design loads the RMI effective design area equation is also quite conservative compared to the analytical solution. The following new effective design area equation is therefore proposed to improve the results.

$$
\begin{equation*}
\frac{A_{e}}{A_{\text {net min }}}=1-(1-Q)\left(\frac{F_{n}}{F_{y}}\right)^{\frac{Q}{1-Q}} \tag{4.5}
\end{equation*}
$$

This proposed equation was developed by modifying the exponential term in Eq. (4.1) so that the results will agree better with the analytical solutions. By multiplying this proposed equation with $F_{n} / F_{y}$ the new relationship between $P_{n} / P_{y}$ and $F_{n} / F_{y}$ is obtained as follows

$$
\begin{equation*}
\frac{P_{n}}{P_{y}}=\frac{F_{n}}{F_{y}}\left(1-(1-Q)\left(\frac{F_{n}}{F_{y}}\right)^{\frac{Q}{1-Q}}\right) \tag{4.6}
\end{equation*}
$$

In Fig. 4.19, the analytical results are compared to the above equation. As can be seen improvement has been made. At the same stress levels Eq. (4.5) simply predicts a larger effective design area than Eq. (4.1) as shown in Fig. 4.20; therefore Eq. (4.6) will give a higher design load than Eq. (4.4) as shown in Fig. 4.21.

The results in this section indicate that unperforated compression elements should be designed by using Eq. (4.5), where the $Q$ factor can be easily computed from Eq. (4.2). If this proposed procedure is used the element design curve will be altered from Eq. (4.2) as shown in Fig. 4.22. Unperforated members and perforated members are studied in the next sections.

### 4.5.2 Unperforated members

Finite element simulations of stub-column tests for unperforated sections were carried out in this study to evaluate the current AISI column design procedure and the RMI effective design area equation. The finite element analysis considers both geometric and material nonlinearities; residual stresses and geometric imperfections are also included in the model. The $Q$ factor obtained from the AISI design approach and from the finite element method is compared in Table 4.18. Cold-formed steel member strength designed according to AISI specification was obtained by using the computer program CU-EWA shown in Appendix H.

It was found that when sections are thin, the AISI design approach is unconservative compared to the analytical results. The reason for this is that when the elements are thin and the radius of the corners in the section is large, local buckling calculations based on the element flat width is unconservative. This problem can be corrected by using a modified AISI design approach as shown in Fig. 4.23. In the modified approach the element width is based on the centerline to centerline distance

between the supporting elements and hence will be larger, the section properties are based on the round corners and hence the design will be more conservative agreeing better with the analytical solution as shown in Table 4.18.

Five methods were used to compute the relationship between $P_{n} / P_{y}$ and $F_{n} / F_{y}$. The first method uses the finite element simulation of the stub-column test, the second method uses the AISI design approach, the third method uses the modified AISI design approach, the fourth method uses the RMI effective design area equation, and the fifth method uses the proposed effective design area equation.

In Figs. 4.24 and 4.28 , the finite element results are compared to the AISI design approach. In Figs. 4.25 and 4.29, the finite element results are compared to the modified AISI design approach. When the modified AISI design approach was used, results similar to the previous stiffened elements study were found; that is, at the ultimate load the analytical results agrees well with the design approach; however at design loads the design approach is quite conservative compared to the analytical solution.

In Figs. 4.26 and 4.30 , the finite element results are compared to the RMI effective design area equation. In Figs. 4.27 and 4.31, the finite element results are compared to the proposed effective design area equation. As can be seen from these figures improvement has been made for the case of thin-walled sections. The results are still quite conservative for thick-walled sections because of the material strain hardening, which was included in the finite element model but is not considered in the design since the component elements are not fully effective.

### 4.5.3 Perforated members

Finite element simulations of stub-column tests for perforated sections were carried out in this study to evaluate the RMI effective design area equation. The $Q$ factor obtained from physical stub-column tests (provided by Unarco Material Handling) and from the finite element method is compared in Table 4.19.

Three methods were used to compute the relationship between $P_{n} / P_{y}$ and $F_{n} / F_{y}$. The first method uses the finite element simulation of the stub-column test, the second method uses the RMI effective design area equation, and the third method uses the proposed effective design area equation.

In Figs. 4.32, 4.34, 4.36, 4.38, and 4.40, the finite element results are compared to the RMI effective design area equation. In Figs. 4.33, 4.35, 4.37, 4.39, and 4.41, the finite element results are compared to the proposed effective design area equation. As can be seen from these figures, the design is more efficient if the proposed equation is used.

Similar changes are also recommended for the effective section modulus equation, which is used for the determination of the member flexural strength. From the current RMI equation

$$
\begin{equation*}
\frac{S_{c}}{S_{\text {net min }}}=1-\frac{(1-Q)}{2}\left(\frac{M_{c} / S_{f}}{F_{y}}\right)^{Q} \tag{4.7}
\end{equation*}
$$

to the following proposed effective section modulus equation

$$
\begin{equation*}
\frac{S_{c}}{S_{\text {net min }}}=1-\frac{(1-Q)}{2}\left(\frac{M_{c} / S_{f}}{F_{y}}\right)^{\frac{Q}{1-Q}} \tag{4.8}
\end{equation*}
$$

By using the proposed equations (Eqs. (4.5) and (4.8)) the member design strength will increase from the current design specification as shown in Figs. 4.42 and 4.43.

### 4.6 MEMBER DESIGN STRENGTH

The proposed equations for determining the effective section properties (Eqs. (4.5) and (4.8)) have altered the member design strength from the current design specification. In this study, unperforated and perforated member strength capacity, under different loading conditions and for various member lengths, were computed using the finite element method, and compared to those values using the RMI specification which uses Eqs. (4.1) and (4.7), and the proposed design approach which uses Eqs. (4.5) and (4.8).

Three C-sections, the same ones used in the previous study Elastic Buckling Strength of Perforated Members, were considered: A-LDR, A-LDR-2, and A-HDR. Their cross sectional geometry is given in Fig. 4.2. The finite element analysis considered both geometric and material nonlinearities. Finite element models range from a member length of 12 to 120 in . with a 6 in . increment between models. Initial conditions of the model involved both flexural residual stresses and geometric imperfections. The magnitude of the flexural residual stresses throughout the thickness in the longitudinal direction is given in Fig. 4.44a. These stresses were assumed to have tension on the outside and compression on the inside of the section. Geometric imperfection was introduced by using the buckling mode shape obtained from the buckling analysis. For short members where local or distortional buckling is critical, buckling mode shape with a maximum imperfection magnitude of one tenth of the thickness was used as the geometric imperfection. For long members where overall buckling is critical as shown in Fig. 4.44b, the geometric imperfection was generated by superimposing the overall buckling and the local buckling mode shape together, where the maximum imperfection magnitudes of these modes are one thousandth of the member length and one tenth of the thickness, respectively. An idealization of the material model that is elastic-plastic with strain hardening was assumed. For Sections

Figure 4.44 Initial conditions of the finite element model (a) Bending residue stresses (b) Geometric imperfections

A-LDR and A-LDR-2, $F_{y}=45 \mathrm{ksi}, F_{u}=59 \mathrm{ksi}, E=29500 \mathrm{ksi}, E_{s t}=E / 45, v=0.3$, and $e_{s t}$ is 15 times the maximum elastic strain. For Section A-HDR the material properties are same but with $F_{y}=47.8 \mathrm{ksi}$.

All three sections were studied as a concentrically loaded compression member, a flexural member subject to bending about the strong axis, and a member subject to combined compressive axial load and bending about the strong axis. Boundary conditions at the ends of the member for all cases were pined condition such that the effective length for flexural buckling of both the strong and weak axis and torsion were equal to the length of the member.

The loads were applied through nodal forces at the ends of the member. To avoid localized failure at the member ends the nodal forces were distributed in to the first three rows of elements. This loading condition is different from the one previously used for the finite simulation of the stub-column test in the Effective Design Area study. In the stub-column test simulation model, nodal displacements were used to apply the load. The reason why in this study nodal forces were selected over applying nodal displacements was to assure that the member ends remain pined condition. Finite element studies of these two loading conditions have shown that the resulting ultimate compression load of the two can be significantly different, especially if the section is locally unstable. The reason for this is that when the uniform displacement is applied, the end surface stresses will not be uniform, and on the other hand when the uniform stresses is applied, the end surface displacement will not be uniform. The ultimate compression load is higher when the uniform displacement is applied rather than when the uniform load is applied. The reason for this is that additional restraints are provided at the ends of the member in the case of applying uniform displacement, preventing the member ends from rotating.

The differences in these two cases are however not significant if the section is locally stable because ultimately the entire section will yield for both cases.

The finite element results are compared with design specifications in Figs. 4.45 through 4.56. The design approach requires the use of the ultimate compression load from a stub-column test to compute the $Q$ factor. Thus, ultimate compression strength obtained from finite element analysis of the member with the shortest length is used.

For the case of compressive axial strength shown in Figs. 4.45, 4.49, and 4.53, it can be seen that the proposed design approach agrees well with the analytical solutions, while the current specification is slightly conservative.

For the case of flexural strength for Sections A-LDR and A-LDR-2 shown in Figs. 4.46 and 4.50 , it can be seen that both approaches are quite conservative for designing flexural members compared to the finite element solution, especially for the very long members. According to the finite element solution, these members have postbuckling strength. The results are also conservative because of the way in which the effective section modulus is computed according to the RMI specification, further investigation of this is given in the next study on the Effective Section Modulus. The conservative results shown in this study can, however, only be obtained if the net section II properties as given Tables 4.2 and 4.3 are used. The reason for this is clear but not explicitly suggested in the specification that the net moment of inertia of the bending axis should be used in the design of the flexural members.

For the case of flexural strength for Section A-HRD shown in Fig. 4.54, even though net moment of inertia is used, both the proposed approach and the RMI approach for this case over estimates the flexural strength. This is because the distortional buckling strength of this section is rather low. The design specification currently does not consider this buckling mode.

For the case of combined compression axial load and bending shown in Figs. 4.47, 4.48, 4.51, 4.52, 4.55, and 4.56, correlations between the finite element results and the interaction equation for beam-column design is given. For a given finite element result, the members strength $P_{u}$ and $M_{u x}$ are substituted in the interaction equation and the resulting axial and flexural strength ratio is plotted. Data points that fall outside the triangle indicate that the interaction equation is conservative. Data points of the proposed design approach are closer to the interaction equation line when compared to the current design procedure, indicating that improvement has been made.

### 4.7 EFFECTIVE SECTION MODULUS

In order to deal with the presence of perforations in a column section, the RMI specification recommends the use of a stub-column test to establish an effective net section area. The area of the effective section is for an axially loaded member failing due to local behavior. The results are also further used to calculate the elastic section modulus of the effective section for determination of the member flexural strength. The objective of this study was to validate this calculated flexural strength by using the finite element approach.

A finite element parametric study of stub-columns subject to bending moment was carried out. The column sections in study were the same ones used in the previous study Effective Design Area, which are given in Table 4.19. The bending moments were applied by applying nodal displacements rotating the end surfaces of the stub-column. The flexural strength was determined for the strong axis bending, weak axis bending with web in tension, and weak axis bending with web in compression as shown in Table 4.20. The analysis in this study considered both geometric and
material nonlinearities. Initial conditions of the model involved both flexural residual stresses and geometric imperfections. Geometric imperfection was introduced by using the buckling mode shape obtained from the buckling analysis with a maximum imperfection magnitude of one tenth of the thickness. An idealization of the material model that is elastic-plastic with strain hardening was assumed.

The RMI specification recommends that nominal flexural strength $M_{n}$ for members not subject to lateral buckling, such as the stub-column under end surface rotations in this study, can be determined as follows:

$$
\begin{equation*}
M_{n}=S_{e} F_{y} \tag{4.9}
\end{equation*}
$$

where

$$
\begin{equation*}
S_{e}=S\left(0.5+\frac{Q}{2}\right) \tag{4.10}
\end{equation*}
$$

$S$ is the elastic section modus of the full unreduced section for the extreme compression or tension fiber at $F_{y}$. The $Q$ factor determined from the finite element approach given in Table 4.19 is used in the above equation to calculate $M_{n}$ and then compared with finite element results of the stub-column under end surface rotations. Results are summarized in Table 4.20. It was found that $M_{n}$ agrees well with the finite element results for the case of strong axis bending, but is rather conservative for weak axis bending. Results are conservative because $M_{n}$ is calculated on the basis of initiation of yielding. Higher values can be obtained by considering the nominal flexural strength $M_{p}$ that is calculated on the basis of inelastic reserve capacity, determined as follows:

$$
\begin{equation*}
M_{p}=Z_{e} F_{y} \tag{4.11}
\end{equation*}
$$

where

$$
\begin{equation*}
Z_{e}=Z\left(0.5+\frac{Q}{2}\right) \tag{4.12}
\end{equation*}
$$

$Z$ is the plastic modulus. Overall $M_{p}$ agrees better with the finite element approach than $M_{n}$ but the results are slightly on the unconservative side; therefore, it is not recommended for design purposes.

### 4.8 MOMENT MAGNIFICATION FACTOR

In the design of beam-columns, primary bending moments due to lateral loads and end moments are multiplied by moment magnification factors to account for the second order effects and the moment gradient in the member. This factor used in the current AISI specification was developed based on the assumption that failure by instability will be in the plane of bending. Thus, the current moment magnification factor does not consider the torsional-flexural failure mode. Generally this may not be the case. The torsional-flexural failure mode is common in thin-walled sections. If it takes place, the bending moments in the elastic beam-column will be unconservative if computed with the current moment magnification factor.

An alternative approach to determine maximum bending moments in elastic beam-columns for the case where it is simply supported with equal end eccentricities is given in this study. Peköz and Celebi (1969) presented an approximate analysis approach for elastic beam-columns with equal end eccentricities. The problem was solved by assuming the deflection functions to satisfy the geometric boundary conditions but with unknown coefficients. The deflection functions were then used in the beam-column differential equations where their unknown coefficients were solved by applying the Galerkin method. The corresponding bending moments about principal axes and twisting moment in the member were obtained in this study by using the resulting deformation from the approach given by Peköz and Celebi (1969).

For the case of a simply supported beam-column, $M_{x \max }$ and $M_{y \max }$ the maximum bending moment about principal $x$ - and $y$-axes occurs at mid-span and $M_{t \text { max }}$ the maximum twisting moment occurs at the member ends. These moments can be computed as follows:

$$
\begin{gather*}
M_{x \max }=M_{x 0}\left\{1+\frac{P\left(P_{e y}-P\right)\left[\left(P_{e t}-P\right) \bar{r}_{0}^{2}+P a_{x}^{2}\right]-P^{3} a_{y}^{2}}{\Delta}\right\}-\frac{M_{y 0} P^{2} P_{e x} a_{x} a_{y}}{\Delta}  \tag{4.13}\\
M_{y \max }=M_{y 0}\left\{1+\frac{P\left(P_{e x}-P\right)\left[\left(P_{e t}-P\right) \bar{r}_{0}^{2}+P a_{y}^{2}\right]-P^{3} a_{x}^{2}}{\Delta}\right\}-\frac{M_{x 0} P^{2} P_{e y} a_{x} a_{y}}{\Delta}  \tag{4.14}\\
M_{t \max }=\frac{P}{\Delta}\left(\frac{\pi G J}{L}+\frac{\pi^{3} E C_{w}}{L^{3}}\right)\left[\left(P_{e y}-P\right) M_{x 0} a_{x}-\left(P_{e x}-P\right) M_{y 0} a_{y}\right] \tag{4.15}
\end{gather*}
$$

where

$$
\begin{gathered}
M_{x 0}=P e_{y} \\
M_{y 0}=P e_{x} \\
\Delta=\frac{\pi}{4}\left|\begin{array}{ccc}
P_{e y}-P & 0 & -P a_{y} \\
0 & P_{e x}-P & P a_{x} \\
-P a_{y} & P a_{x} & \bar{r}_{0}^{2}\left(P_{e t}-P\right)
\end{array}\right|
\end{gathered}
$$

$P$ is the applied eccentric load, $M_{x 0}$ and $M_{y 0}$ are the end bending moment about the $x$ - and $y$-axes, respectively. Definitions of the other variables and derivation of Eqs. (4.13) to (4.15) are given in the Appendix C and D.

Consider the case when the beam-column section has one plane of symmetry and $P$ is applied in that plane. Assume that $y$-axis is the axis of symmetry. Then $a_{x}=e_{x}=0$, Eqs. (4.14) and (4.15) will give $M_{y \max }=M_{t \max }=0$, and Eq. (4.13) becomes

$$
\begin{equation*}
M_{x \max }=\frac{C_{m x} M_{x 0}}{(1-\alpha)} \approx M_{x 0} \sec \left(\frac{\pi}{2} \sqrt{\alpha}\right) \tag{4.16}
\end{equation*}
$$

where

$$
\begin{gathered}
C_{m x}=1+0.273 \alpha \\
\alpha=P / P_{e x}
\end{gathered}
$$

$C_{m x} /(1-\alpha)$ is the moment magnification factor which amplifies the end moment $M_{x 0}$ to account for the second order effects. This is the same moment magnification factor given by the AISI specification but with an approximation of $C_{m x}=1$ for the same corresponding boundary conditions.

Consider another case when the Section A-LDR is subjected to a compression load with eccentricities: $e_{x}=0$ and $e_{y}=1$ in. as shown in Fig. 4.57. In this case $M_{x \max }$ from Eq. (4.13) will not be the same as from using the moment magnification factor given by the AISI specification. Fig. 4.58 compares the results. It can be seen that the AISI approach gives an unconservative $M_{x \max }$. This is because Eq. (4.13) has the level of $P$ limited at the elastic critical axial load $P_{e}$, agreeing with the actual behavior in which the member will buckle by torsional-flexural at this load. But the AISI approach has it limited at the flexural buckling load $P_{e x}$ instead. Contour plots given in Fig. 4.57 can be used to obtain $P_{e}$ for the different load eccentricities. The failure mode for this member is by combined bending and torsion. The cross section between the supports will undergo translation and rotation. Therefore, in addition to the bending moment about the $x$-axis directly developing from the applied loads, the bending moment about $y$-axis and the twisting moment will also exist. The maximum values of these moments are obtained by using Eqs. (4.14) and (4.15). Results are shown in Figs. 4.59 and 4.60 , respectively.

Figure 4.59 Bending moment about the $y$-axis

Figure 4.60 Twisting moment about the $z$-axis

In this study, equations for determining the maximum bending moments in elastic beam-columns for the case where it is simply supported with equal end eccentricities and failure is by torsional-flexural buckling are given. Developing simple means for determining the bending moments in beam-columns with unequal end eccentricities, subject to support translation, and failure is by torsional-flexural buckling would be useful for the design of cold-formed steel frames. However, preliminary studies have shown that the equations become very complicated and may not be practical for the design purpose.

### 4.9 CONCLUSIONS

A critical review of the RMI specification for member design was carried out in this chapter. A total of seven studies were carried out. In the first study Elastic Buckling Strength of Perforated Members, numerous finite element elastic buckling analyses of perforated member were carried out. Results indicate that increasing the presence of perforations in the section will reduce the buckling strength. To take this into account, instead of using the unperforated section properties to predict the buckling strength of perforated sections, as assumed in the current design specification, better results can be obtained by using the weighted section, or the average section properties for torsional-flexural buckling, the average section properties for lateral buckling, and the net moment of inertia section properties for flexural buckling.

In the second study Torsional-Flexural Buckling, the torsional-flexural buckling equation used in the current design provision was evaluated by comparing the results with finite element solutions. It was found that the elastic buckling load obtained from using the buckling equation is usually conservative compared to the
finite element results. The reason for this is that the buckled shape assumptions made in the buckling equation are inconsistent with the actual buckled shape. This leads to errors underestimating the elastic buckling load of member and has proven to be a source of the conservatism in the current design provision.

In the third study Effective Lengths, the effective length factors used in the current design provision were evaluated by comparing the results with finite element solutions. It was found that the recommended value of $K_{y}$ taken as one is in general conservative while $K_{t}$ taken as 0.8 is in most cases reasonable, providing that the upright frame has adequate braces and the column base is constrained against twisting.

In the fourth study Effective Design Area, finite element simulation of stub-column tests were carried out to evaluate the current effective design area equation and effective section modulus equation. Modifications of these equations are suggested. The effective design area equation of the RMI specification, Eq. (4.1), should be modified to the proposed equation, Eq. (4.5). The effective section modulus equation of the RMI specification, Eq. (4.7), should be modified to the proposed equation, Eq. (4.8).

In the fifth study Member Design Strength, unperforated and perforated member strength capacity, under different loading conditions and for various member lengths, was computed using the finite element method, and compared to those values using the RMI specification, which uses Eqs. (4.1) and (4.7), and the proposed design approach, which uses Eqs. (4.5) and (4.8). It was found that the compressive axial strength and the beam-columns strength designed according to the proposed design approach agrees better to the finite element results than the current design procedure does. Flexural strength design according to either design approach is quite conservative compared to the finite element results, if distortional buckling failure mode does not take place.

In the sixth study Effective Section Modulus, finite element simulation of stubcolumn tests under bending moments were carried out to evaluate the current RMI procedures for determining the member flexural strength. It was found that current procedure for calculating the nominal flexural strength on the basis of initiation of yielding $M_{n}$ for members not subject to lateral buckling is conservative, especially for weak axis bending. Equations for determining the nominal flexural strength on the basis of inelastic reserve capacity $M_{p}$ are given in this study and have been shown to agree better with the finite element results than $M_{n}$, but the results are slightly on the unconservative side, therefore it is not recommended for design purposes.

In the seventh study Moment Magnification Factor, equations for determining the maximum bending moments in elastic beam-columns for the case where it is simply supported with equal end eccentricities and failure is by torsional-flexural buckling are given. Determining the maximum moments for this boundary condition using the current moment magnification factor suggested by the AISI specification has been shown to give unconservative results if the member failure is by torsionalflexural. This unconservatism in the AISI moment magnification factor by itself, however, does not suggest that current design procedures for beam-columns is unconservative. On the contrary, as to be shown in Chapter 5, in practice when the AISI moment magnification factor is used with the interaction equation to design beam-columns current design procedure is very conservative.

## Cold-Formed Steel Frames

### 5.1 INTRODUCTION

The behavior of industrial storage racks depends on how the three individual components discussed in the previous chapters: column bases, beam to column connections, and members perform interactively with each other. Thus the frame behavior can become very complex. Many parameters such as semi-rigid nature of connections, presence of significant perforations, and susceptibility to local buckling and torsional-flexural buckling are part of the cause. As to which method of analysis is best to solve this problem will certainly depend on the tools available to the designer. The analysis model can be as simple as using a sub-structure model such as isolating the column and using the alignment chart, or as sophisticated as using numerical methods to analyze the entire frame. With the availability of powerful computers and software, the latter approach has become more attractive, allowing more complex and efficient designs. In this chapter results will be presented from studies which were carried out to evaluate the current effective length approach and to examine the
notional load approach as an alternative design procedure, as well as to review current guidelines for methods of analysis and for using numerical methods for structural analysis, such as elastic buckling analysis and second-order elastic analysis considering semi-rigid connections.

### 5.2 ELASTIC BUCKLING STRENGTH OF PALLET RACKS

The AISI, AISC, and RMI specifications use the effective length approach for assessing frame stability. It is essential that effective lengths and the elastic buckling load of members are accurately determined in the effective length approach. Parameters that influence the value of $K_{x}$ for column flexural buckling were examined in this study. The alignment chart and the AISI torsional-flexural buckling provisions, used to obtain the effective lengths and elastic buckling load of members were also evaluated.

### 5.2.1 Effective Length $K_{x}$

Parameters that influence the value of $K_{x}$ for column flexural buckling in the direction perpendicular to the upright frames can be summarized in three categories as shown in Fig. 5.1.

The first category is the number of bays and stories. For fully loaded frames, as the number of bays increases so does the value of $K_{x}$ because the supporting action of light loaded end frame columns diminishes, and as the number of stories increases so does the value of $K_{x}$ because the difference in loads in the bottom story and the second story columns decreases.

The second category is the loading conditions. Adding horizontal forces on a fully loaded frame makes insignificant changes to the value of $K_{x}$ because the

Number of bays and stories

$\underline{\text { Loading conditions }}$

Section properties and connection stiffness

Figure 5.1 Parameters that influences the value of $K_{x}$ for column flexural buckling
additional horizontal force makes insignificant changes to the level of axial loads on the interior columns. As the number of loaded bays increases so does the value of $K_{x}$; therefore, a fully loaded frame is always the most critical load case as far as elastic buckling is concerned.

The third category is the section properties and connection stiffness. As the column size increases so does the value of $K_{x}$; however as the beam size and the connection stiffness increases the value of $K_{x}$ will decrease because additional restraint from the beam and connection stiffness helps prevent the frame from sidesway buckling.

A parametric study was carried out to investigate the effects of the loading conditions on the frame stability. Two loading sequences on a 6 -bay by 6 -story pallet rack shown in Fig. 5.2 were studied. One is the best possible loading sequence which will minimize the frame instability while the other is the worst possible loading sequence which will maximize the frame instability. As can been seen in Fig. 5.2, the best loading sequence is one which starts loading from the lower stories, while the worst loading sequence is one which does the opposite; that is, it starts loading from the upper stories.

The resulting effects that these two loading sequences have on the frame stability are plotted in Fig. 5.3 where $W_{\text {Loadi }}$ is the elastic buckling gravity load per bay when $i$ number of bays have been loaded, and $W_{\text {Load 36 }}$ is the elastic buckling gravity load per bay when all bays have been loaded. As can be seen in this figure, it is better to start accessing the products from the upper stories while keeping the lower stories loaded until last.

### 5.2.2 Alignment Chart and Torsional-flexural Buckling Provisions

The objective of this study was to evaluate the alignment chart and the AISI torsional-flexural buckling provisions. The 6-bay by 3-story pallet rack as shown in Fig. 5.4 was used as the vehicle for carrying out this study. The value of $K_{x}$ was determined from the alignment chart and compared to those values determined more accurately from a finite element flexural buckling analysis. The finite element modeling assumptions are as follows: the column base fixity was modeled by torsional springs with its stiffness determined from the proposed base fixity equation given in Chapter 2 and the beam to column connection stiffness $K_{\theta}$ was also modeled by torsional springs.

In this study $K_{\theta}$ was varied and the corresponding $K_{x}$ was determined for the bottom story and the second story middle column. The results are as shown in Fig. 5.5. It was found that the alignment chart was unconservative when used for the bottom story column with low $K_{\theta}$ values, and was always too conservative when used for the second story column. The reason for this is that, in actual practice the alignment chart assumptions are rarely satisfied exactly. Such violations lead to errors making the results unconservative for the bottom story column even when reductions in beam stiffness have already been made to reflect the semi-rigid nature of the connections, and the results are too conservative for the second story column because the high base fixity value was not accounted for in the alignment chart. Thus, the alignment chart is inaccurate when differences between the base fixity and the connection flexibility is high.

The column section used in the pallet rack shown in Fig. 5.4 was a $3 \times 3$ C-section with its axis of symmetry perpendicular to the aisle. Torsional-flexural buckling is normally the critical buckling mode for this section. The buckling load is usually determined by either using the AISI torsional-flexural buckling provisions or

Figure 5.4 Storage rack in study

Figure 5.5 Evaluation of the Alignment chart

Figure 5.6 Evaluation of the torsional-flexural buckling equation
more accurately obtained by performing an elastic buckling analysis of the entire frame. The results of using these two approaches to determine the buckling load of the bottom story middle column are compared in Fig. 5.6. The AISI buckling equation is computed based on the values of $K_{x}$ determined from flexural buckling analysis, which were given in Fig. 5.5, and $K_{t}=0.717$ determined from a torsional buckling analysis. It was found that the AISI torsional-flexural buckling provisions become gradually more conservative as the value of $K_{\theta}$ increases.

### 5.3 PLUMBNESS

Out-of-plumb installation of frames creates secondary moments in the columns causing frame instability. The RMI specification recommends that the frame initial out-of-plumbness should not be more than 0.5 inches in 10 feet ( $\psi=1 / 240$ ). The following study was carried out to investigate different initial out-of-plumb modes and the impact it has on the load carrying capacity of frame.

Five frame initial out-of-plumb modes as shown in Fig. 5.8 were considered. The initial out-of-plumbness of the first three modes are within the RMI guidelines while the last two modes are not because the column imperfection gradient has exceeded 0.5 inches in 10 feet.

The pallet rack shown in Fig. 5.7 was used as the vehicle for carrying out this study. Finite element analysis was performed to compute the load carrying capacity of the frame for the different initial out-of-plumb modes, and also for the different frame beam to column connection stiffnesses to cover a wide range of column $K_{x}$ values. Results are compared with respect to Mode 0 as shown in Fig. 5.9. Finite element modeling assumptions include using a three-dimensional model, using open-section beam elements to model the columns and braces, using linear torsional springs to

Figure 5.7 Storage rack in study

Figure 5.8 Different modes of frame initial out-of-plumb

Figure 5.9 Effect of initial out-of-plumb on the load carrying capacity of the frame
model the connection stiffness, using the proposed base fixity equation given in Chapter 2 to compute the stiffness of the column base, and using an elastic-plastic material model $F_{y}=55 \mathrm{ksi}$, and $E=29500 \mathrm{ksi}$. The finite element analysis considers both geometric and material nonlinearities.

As can be seen in Fig. 5.9, the load carrying capacity of Mode 1 and 2 is always higher than Mode 0 ; therefore, as long as the actual frame initial out-ofplumbness is within the RMI guideline, it is always conservative to assume Mode 0 in the design analysis. The results of Mode 3 and 4 clearly show why the initial out-ofplumbness of 0.5 inches in 10 feet should be interpreted as restrictions of the imperfection gradient of the column rather than the absolute maximum column imperfection tolerances.

### 5.4 MOMENT MAGNIFICATION FACTOR

In the design of beam-columns, the relationship between the required axial compression strength $P_{u}$ and flexural strength $M_{u}$ for the member under consideration could be obtained by performing a second-order elastic analysis, or alternatively approximated by performing a first-order elastic analysis using moment magnification factors as follows:

$$
\begin{equation*}
M_{u}=B_{1} M_{n t}+B_{2} M_{l t} \tag{5.1}
\end{equation*}
$$

where $M_{n t}$ and $M_{l t}$ are the required flexural strength in the member obtained from first-order elastic analysis assuming the frame to have no lateral translation and assuming the frame to have lateral translation, respectively. $B_{1}$ and $B_{2}$ are moment magnification factors which are needed to account for the second-order effects. The objective of this study was to evaluate the AISI and the AISC recommended
sidesway moment magnification factor $B_{2}$. The AISC specification gives an expression for $B_{2}$ as

$$
\begin{equation*}
B_{2}=\frac{1}{1-\frac{\sum P_{u}}{\sum P_{e x}}} \tag{5.2}
\end{equation*}
$$

or

$$
\begin{equation*}
B_{2}=\frac{1}{1-\sum P_{u}\left(\frac{\Delta_{o h}}{\sum H L}\right)} \tag{5.3}
\end{equation*}
$$

where $\Sigma P_{u}$ is the required axial strength of all columns in the a story, $\Delta_{o h}$ is the lateral inter-story deflection, $\Sigma H$ is the sum of all story horizontal forces producing $\Delta_{o h}$, $L$ is the story height, and $\Sigma P_{e x}$ the elastic flexural buckling strength of all columns in the story. The AISI specification accounts for the second-order effects by multiplying the moment term in the interaction equation by $C_{m x} / \alpha_{x}$, where $C_{m x}$ is 0.85 for sidesway and $\alpha_{x}=1-P_{u} / P_{e x}$, which is equivalent to having $B_{2}$ as

$$
\begin{equation*}
B_{2}=\frac{0.85}{1-\frac{P_{u}}{P_{e x}}} \tag{5.4}
\end{equation*}
$$

the value of $P_{u} / P_{e x}$ in the above equation and the value of $\sum P_{u} / \sum P_{e x}$ in Eq. (5.2) are the same when their parameters are obtained from performing first-order analysis and elastic buckling analysis, therefore Eq. (5.2) and Eq. (5.4) differ only by a factor of 0.85 .

The developing moment at the base of the center column of the pallet rack shown in Fig. 5.7 was investigated. All bays are equally loaded causing zero $M_{n t}$ in the center column; therefore, the moment magnification factor $B_{1}$ is not needed; $M_{u}$ arises only from the lateral translation of the frame which is due to the frame initial out-of-plumbness. Frame initial out-of-plumb mode 0 as shown in Fig. 5.8 is

Figure 5.10 Frame with $K_{\theta}=300 \mathrm{kips}$-in. - Correlation between second-order elastic analysis and moment magnification factors

Figure 5.11 Frame with $K_{\theta}=600$ kips-in. - Correlation between second-order elastic analysis and moment magnification factors

Figure 5.12 Frame with $K_{\theta}=1200$ kips-in. - Correlation between second-order elastic analysis and moment magnification factors

Figure 5.13 Frame with $K_{\theta}=$ Rigid - Correlation between second-order elastic analysis and moment magnification factors
assumed. The relationship between $P_{u}$ and $M_{u}$ at the base of the center column obtained from second-order elastic analysis is used as a basis for evaluating Eqs. (5.2), (5.3), and (5.4). The results are given for four beam to column connection stiffnesses: $K_{\theta}=300,600,1200$ kips-in., and rigid as shown in Figs. 5.10 through 5.13. As can been from these figures, Eq. (5.4) agrees better with the second-order elastic analysis than Eqs. (5.2) and (5.3) do. Eq. (5.2) is slightly more conservative than the results from second-order elastic analysis and Eq. (5.4), while Eq. (5.3) is unconservative compared with the results from second-order elastic analysis when used for semi-rigid frames. If the designer does not use second-order elastic analysis to obtain the required member strength, the result from this study suggests that the AISI sidesway moment magnification factor Eq. (5.4) should be used to account for the sidesway second-order effects.

### 5.5 NONLINEAR ANALYSIS OF PALLET RACKS

The behavior of industrial storage racks depends on how the three components: column bases, beam to column connections, and members perform interactively with each other. These components and the slender nature of the structure are sources of nonlinearity, thus the frame behavior can become very complex. Different levels of structural analysis were carried out to investigate four fundamental modeling assumptions: model geometry, material property, column base, and beam to column connection. Five different analysis levels as summarized in Table 5.1, all of which are second-order analyses, were performed on the pallet rack shown in Fig. 5.4 to investigate the different nonlinear responses. Definitions of the four fundamental modeling assumptions are as follows:

Table 5.1 Different Levels of Structural Analysis

| Analysis <br> type | Model <br> geometry | Material <br> property | Column <br> base | Beam to column <br> connection |
| :---: | :---: | :---: | :---: | :---: |
| A | 3D | Inelastic | Inelastic | Inelastic |
| B | 3D | Inelastic | Inelastic | Elastic |
| C | 3D | Inelastic | Elastic | Elastic |
| D | 3D | Elastic | Elastic | Elastic |
| E | 2D | Elastic | Elastic | Elastic |

Figure 5.14 Different levels of structural analysis

Model geometry: The 3D frame refers to modeling the entire pallet rack as a space frame and open-section beam elements are used to model the columns and braces, while 2D frame refers to modeling the pallet rack as a plane frame with only in-plane beam elements.

Material property: The inelastic material model refers to having all components modeled as elastic-plastic material with strain hardening. $F_{y}=55 \mathrm{ksi}$, $F_{u}=70 \mathrm{ksi}, E=29500 \mathrm{ksi}, E_{s t}=E / 45, v=0.3$, and $e_{s t}$ is 15 times the maximum elastic strain.

Column base: The elastic column base refers to using torsional springs to model the base fixity where its stiffness is determined from the proposed base fixity equation given in Chapter 2. The behavior of the column base is generally elastic as long as the base plate remains in full contact with the floor. Once the column base's moment to axial load ratio reaches its upper bound limit, which is when the base plate starts to overturn, the base fixity will decrease dramatically. The inelastic column base in this study refers to modeling the column base with a double axial spring model as shown in Fig. 5.15b. This model not only has the same stiffness as the elastic case but will also capture the upper bound limit of base fixity behavior. Further detail on how the double axial spring model was developed is given in Appendix A.

Beam to column connection: The inelastic beam to column connection means considering the connection to be semi-rigid setting the moment and rotation relationship as elastic-plastic. In this study the connection stiffness $K_{\theta}=270$ kips-in./rad and ultimate connection moment capacity $M=6$ kips-in. was assumed.

Results for the different levels of analysis are given in Fig. 5.14. Analysis type A is considered to best represent the actual frame's behavior. As the levels of analysis decrease, higher load carrying capacity of the frame is obtained. This result is as

Figure 5.15 Base fixity model (a) Torsional spring (b)-(e) Double axial spring
expected; therefore, when simple analytical models such as analysis type E are used for design special considerations are necessary to account for the effects that the analysis is incapable of simulating; for example, calculating the column torsionalflexural buckling load, using the beam-column interaction equation, and monitoring moments at the beam to column connections and column bases.

### 5.6 EFFECTIVE LENGTH APPROACH AND NOTIONAL LOAD APPROACH FOR COLD-FORMED STEEL FRAME AND BEAMCOLUMN DESIGN

The effective length approach and the notional load approach are used in many specifications and standards for steel frame design. The differences between these two approaches are the way in which the physical nature of the column and frame imperfections are accounted for in the design. For more background information on the philosophy behind these two design approaches, the reader is referred to ASCE (1997). The objective of this study was to compare the effective length approach and the notional load approach for accuracy and appropriateness for coldformed steel frame and beam-column design. The storage rack industry currently uses the effective length approach. Design procedures of these two approaches are as follows:

## APPROACH 1 - EFFECTIVE LENGTH APPROACH

## - Concentrically Loaded Compression Members

The column is considered to be a concentrically loaded compression member. The axial load carrying capacity of the member is determined according to the effective length approach using the following equation:

$$
\begin{equation*}
P_{u}=\phi_{c} P_{n} \tag{5.5}
\end{equation*}
$$

This approach relies significantly on the prediction of the critical buckling load of the member. The critical buckling load is usually determined by using the AISI torsionalflexural buckling provisions, or could be more accurately obtained by performing an elastic buckling analysis. Both procedures were investigated.

Approach $1 \boldsymbol{a}$ - the elastic buckling load was computed by using the AISI torsional-flexural buckling provisions with the value of $K_{x}$ determined from the alignment chart or more accurately determined from an elastic flexural buckling analysis, and the values of $K_{y}$ and $K_{t}$ are assumed equal to 1 and 0.8 , respectively.

Approach $\mathbf{1 b}$ - the elastic buckling load was obtained directly from a finite element elastic buckling analysis. This yielded a more accurate design than Approach $1 a$ because as has been illustrated in Charter 4, the torsional-flexural elastic buckling load obtained from using the AISI buckling provisions can sometimes be quite conservative compared to the more accurate value obtained from performing the elastic buckling analysis.

## - Combined Compressive Axial Load and Bending

The member is considered to be subject to a combined compressive axial load and bending. The axial compression strength $P_{u}$ and flexural strength $M_{u}$ for the member is determined according to the effective length approach using the following equation:

$$
\begin{equation*}
\frac{P_{u}}{\phi_{c} P_{n}}+\frac{M_{u}}{\phi_{b} M_{n}} \leq 1 \tag{5.6}
\end{equation*}
$$

Moment magnification factors are not included in the above interaction equation because the second-order elastic analysis is used to obtain $P_{u}$ and $M_{u}$. Moment
magnification factors are needed if the first-order analysis is used. Second-order elastic analysis is conducted on a frame with story-out-of plumbness of 0.5 inches in 10 feet ( $\psi=1 / 240$ ) as suggested by the RMI Specification. A simple plane frame (2D) model as shown in Fig. 5.16a could be used for the second-order elastic analysis but semi-rigid connections must be considered. Second-order elastic analyses and elastic buckling analyses of semi-rigid frames could be performed by using the computer program CU-SRF shown in Appendix H. This approach relies significantly on the prediction of the critical buckling load of the member. The two different procedures for obtaining critical buckling load as mentioned previously in Approaches $1 a$ and $1 b$ were investigated.

Approach 1c - the elastic buckling load was computed by using the AISI torsional-flexural buckling provisions with the value of $K_{x}$ determined from the alignment chart or more accurately determined from elastic flexural buckling analysis, and the value of $K_{y}$ and $K_{t}$ were assumed equal to 1 and 0.8 , respectively.

Approach 1d - the elastic buckling load was obtained directly from an elastic buckling analysis.

## APPROACH 2 - NOTIONAL LOAD APPROACH

The member is considered to be subject to a combined compressive axial load and bending. The axial compression strength $P_{u}$ and flexural strength $M_{u}$ for the member is determined according to the notional load approach using the following equation:

$$
\begin{equation*}
\frac{P_{u}}{\phi_{c} P_{n(L)}}+\frac{M_{u}}{\phi_{b} M_{n}} \leq 1 \tag{5.7}
\end{equation*}
$$

Figure 5.16 (a) Effective length approach (b) Notional load Approach
where $P_{n(L)}$ is the axial strength computed based on the values of $K_{x}$ and $K_{y}$ both assumed equal to one, and $K_{t}$ assumed equal to 0.8 . The AISI torsional-flexural buckling provisions are used to compute the elastic buckling load. Moment magnification terms are not included in the above interaction equation because the second-order elastic analysis is used to obtain $P_{u}$ and $M_{u}$. Moment magnification factors are needed if the first-order analysis is used. Second-order elastic analysis is conducted on a geometrically perfect frame subject to notional horizontal load $\xi W_{\text {story }}$ at each story, where $W_{\text {story }}$ is the gravity load at that story, and $\xi$ is the notional load parameter. A simple plane frame (2D) model as shown in Fig. $5.16 b$ could be used for the second-order elastic analysis but semi-rigid connections must be considered. Performing the second-order elastic analysis on a frame with initial out-of plumbness as shown Fig. $5.16 a$ or on a geometrically perfect frame subject to notional horizontal loads as shown Fig. $5.16 b$ is the same if $\psi$ is equal to $\xi$ because they are statically equivalent. Therefore, the only difference between the effective length approach and the notional load approach is the value of the column axial strength used in the interaction equation because it is a function of $K_{x}$. The column flexural strength $M_{n}$ is not the function of $K_{x}$ when the column is bending in the direction perpendicular to the upright frames.

The notional load approach relies significantly on the selection of the notional horizontal load and the flexural stiffness of the analysis model. Three procedures for selecting the notional horizontal load and the flexural stiffness of the analysis model were investigated.

Approach $2 \boldsymbol{a}$ - the notional load parameter $\xi$ was assumed equal to the frame initial out-of-plumbness. The RMI specification recommends that the frame initial out-of-plumbness should not be more than 0.5 inches in 10 feet, therefore in this approach $\xi$ was assumed equal to $1 / 240$.

Approach $2 \boldsymbol{b}$ - the notional load parameter $\xi$ was determined from

$$
\xi= \begin{cases}\left(K_{x}-1\right) / 168, & 1<K_{x}<1.7  \tag{5.8}\\ 1 / 240, & K_{x} \geq 1.7\end{cases}
$$

Approach $2 \boldsymbol{c}$ - the notional load parameter $\xi$ was assumed equal to $1 / 240$ and the second-order elastic analysis was performed on a reduced flexural stiffness model. A $10 \%$ reduction in the flexural stiffness was proposed. This was done by using a reduce flexural stiffness $E I *$ for all members and connections in the analysis model

$$
\begin{equation*}
E I^{*}=0.9 E I \tag{5.9}
\end{equation*}
$$

where $E$ is the modulus of elasticity, and $I$ is the moment of inertia about the axis of bending. When the moment magnification factors are used to approximate the relationship between $M_{u}$ and $P_{u}$ from first-order analysis, and the first-order analysis is based on a reduced flexural stiffness model, Eq. (5.7) becomes

$$
\begin{equation*}
\frac{P_{u}}{P_{e x(L)}}+\frac{C_{m x} M_{u}}{\left(1-\frac{P_{u}}{P_{e x} *}\right) M_{n}} \leq 1 \tag{5.10}
\end{equation*}
$$

where $P_{e x} *$ is the elastic flexural buckling load based on $E I^{*}$, thus $P_{e x}{ }^{*}=0.9 P_{e x}$

### 5.6.1 Isolated rotationally restrained sway column

A parametric study was carried out to compare the effective length approach and the notional load approach for accuracy and appropriateness for beam-column design. An isolated rotationally restrained sway column as shown in Fig. $5.17 a$ was used as the vehicle for carrying out the parametric study. The parameters included: nine column sections as shown in Fig. 5.18, three material yield stresses (33, 55, and 70 ksi , and twenty different rotational end-restraints as given in Table 5.2. Combinations of these parameters yielded a total of 540 beam-column configurations.

The finite element method, which considers both geometric and material nonlinearities, was used as the basis for evaluating the accuracy of the design approaches. The finite element modeling assumptions included using a threedimensional model, using open-section beam elements to model the open-section columns, using linear torsional springs to model the rotational end-restraints for bending about the major axis, using pin-ended supports for bending about the minor axis and for twisting, using a combination of the out-of-straightness and the out-ofplumbness as shown in Figs. $5.17 b$ and $5.17 c$ for the member initial geometric imperfection, and using an elastic-plastic material model.

The correlations between the different design approaches and the finite element results are summarized in Appendix E Table E. 1 where $P_{1 a}, P_{1 b}, P_{1 c}, P_{1 d}$, $P_{2 a}, P_{2 b}$, and $P_{2 c}$ are the axial load carrying capacity of the member obtained by using the Approaches $1 a, 1 b, 1 c, 1 d, 2 a, 2 b$, and $2 c$, respectively. $P_{\text {FEM }}$ is the axial load carrying capacity of the member obtained by using the finite element method. In practice, the resistance factor $\phi_{c}$ is equal to 0.85 , and $\phi_{b}$ is equal to 0.90 or 0.95 ; these values are, however, for research purposes in this study all assumed equal to one. In practice, the value of $K_{t}$ for column torsional buckling is assumed equal to 0.8 if braces constrain the column from twisting. This value was, however in this study assumed equal to one, because the column was simply supported for twisting. The statistical summary of Table E. 1 is given in Table 5.3. Design examples for the difference approaches are given in the Appendix F.

The results, which are given in Appendix E Table E.1, are also plotted in Figs. 5.19 through 5.25 where the finite element analysis was used as the basis for evaluating the accuracy of the different design approaches. As can be seen in these figures, Approaches $1 c, 1 d, 2 a, 2 b$, and $2 c$ are conservative compared to the finite element results while the Approaches $1 a$ and $1 b$ have a few unconservative designs.

Figure 5.22 Correlation between the Effective Length Approach (Approach 1d) and the FEM results

Figure 5.23 Correlation between the Notional Load Approach (Approach 2a) and the FEM results

Figure 5.24 Correlation between the Notional Load Approach (Approach 2b) and the FEM results

Figure 5.25 Correlation between the Notional Load Approach (Approach 2c) and the FEM results

Comparison between Approach $1 a$ and $1 b$ indicates that $1 b$ agrees better with the finite element results than $1 a$ does. Approach $1 a$ has lower design loads than $1 b$ because of the conservatism in the AISI torsional-flexural buckling provisions. Both Approaches $1 a$ and $1 b$ have a few unconservative designs because the secondary moment coming from the member out-of-plumbness was not considered in the design.

Comparison between Approach $1 c$ and $1 d$ indicates that $1 d$ agrees better with the finite element results than $1 c$ does. Approach $1 c$ has lower design loads than $1 d$ because of the conservatism in the AISI torsional-flexural buckling provisions. Overall both Approaches $1 c$ and $1 d$ predict a very conservative design.

Comparison between Approach $1 a$ and $1 c$ indicates that even though the overall result of $1 a$ agrees better with the finite element results than $1 c$ does, Approach $1 c$ is still more appropriate for design because it accounts for the secondary moments having no unconservative designs.

Comparison between Approach $2 a$ and $2 b$ indicates that $2 b$ agrees better with the finite element results than $2 a$ does. When $K_{x}$ is less than 1.7, Approach $2 b$ will have higher design loads than Approach 2a because it uses less notional horizontal loads according to Eq. (5.8). Implementation of Approach $2 b$, however, must be considered carefully, because Eq. (5.8) was developed based on the design calibration of a limit number of frame configurations. Thus, it may not always be applicable.

Comparison between Approach $2 a$ and $2 c$ indicates that even though the overall result of $2 a$ agrees better with the finite element results than $2 c$ does, Approach $2 c$ provides a more consistent conservatism in its design across the different $K_{x}$ values. In Approach $2 c$, a $10 \%$ reduction in the flexural stiffness of the analysis model was made; this has an effect mostly on the beam-columns, which have high $K_{x}$ values, causing a $10 \%$ reduction in the design strength.

Comparison between Approaches 1 and 2 indicates that overall Approach 2, which is the notional load approach, agrees better with the finite element results than Approach 1, which is the effective length approach. Among the three notional load approaches: $2 a, 2 b$, and $2 c$, it is recommended that Approach $2 c$ be considered as an alternative means for cold-formed steel frame and beam-column design. Approach $2 c$, which is the notional load approach with flexural stiffness reduction, provides a reliable consistently conservative design across wide ranges of beam-column configurations. The reason for choosing this approach, even though the overall results of Approaches $2 a$ and $2 b$ agree better with the finite element results, is because the $10 \%$ reduction in the flexural stiffness is needed to account for the strength reduction due to member initial crookedness for the same reasons that in the effective length approach the column axial strength is designed according to the following equation $F_{n}=0.877 F_{e}$ for $\lambda_{c} \geq 1.5$. This equation when used in the notional load approach to compute $P_{n(L)}$ does not account for the structural strength reduction because $P_{n(L)}$ is computed based on $K_{x}$ equal to one. $P_{u}$ and $M_{u}$, which are used in the interaction equation, obtained based on a reduced flexural stiffness analysis model do account for the structural strength reduction.

### 5.6.2 Interaction Equation

The difference between the effective length approach and the notional load approach is the value of the column axial strength used in the interaction equation because it is a function of $K_{x}$. The column flexural strength $M_{n}$ is not the function of $K_{x}$. To explain how the interaction equation works differently for these two design approaches one can classify the failure modes for beam-columns into three categories as follows:

The first category is failure by material yielding. The design of stocky columns having this failure mode are independent of the members elastic buckling load. The interaction equation used for this design can be simplified as follows:

$$
\begin{equation*}
\frac{P_{u}}{P_{y}}+\frac{M_{u}}{M_{n}} \leq 1 \tag{5.11}
\end{equation*}
$$

where $P_{y}$ is the axial strength at yield stress. The value of $P_{y}$ is independent of the elastic buckling load; therefore, the same design load is obtained using the effective length approach or the notional load approach.

The second category is failure by elastic buckling. The load carrying capacity of slender columns having this failure mode is very close to its elastic buckling load. The interaction equation used for this design can be simplified as follows:

$$
\begin{equation*}
\frac{P_{u}}{P_{e}}+\frac{M_{u}}{M_{n}} \leq 1 \tag{5.12}
\end{equation*}
$$

where $P_{e}$ is the elastic buckling load. For the case when flexural buckling is the critical buckling mode, and the moment magnification factor is used instead of performing the second-order analysis, further simplification can be made as follows:

$$
\begin{equation*}
\frac{P_{u}}{P_{e x}}+\frac{C_{m x} M_{u}}{\left(1-\frac{P_{u}}{P_{e x}}\right) M_{n}} \leq 1 \tag{5.13}
\end{equation*}
$$

where $P_{e x}$ is the elastic flexural buckling load and $C_{m x}$ is a constant coefficient. The above interaction equation is for designing beam-columns according to the effective length approach. For designing beam-columns according to the notional load approach the following equation is used instead:

$$
\begin{equation*}
\frac{P_{u}}{P_{e x(L)}}+\frac{C_{m x} M_{u}}{\left(1-\frac{P_{u}}{P_{e x}}\right) M_{n}} \leq 1 \tag{5.14}
\end{equation*}
$$

where $P_{e x(L)}$ is the elastic flexural buckling load computed based on $K_{x}$ being equal to one. As can be readily seen from Eqs. (5.13) and (5.14), the design load $P_{u}$ obtained from either of these equations will never exceed $P_{e x}$ because of the moment magnification factor term. The notional load approach will, however, allow a higher design load than the effective length approach because the value of $P_{e x(L)}$ is higher than $P_{e x}$; that is, $P_{u}$ obtained from the notional load approach will be closer to the estimated value $P_{e x}$ making it more accurate than the effective length approach. This remark also holds true when member failure is by torsional-flexural buckling as can be seen by comparing the results of Figs. 5.21 and 5.23 for the high $K_{x}$ value cases.

The third category is failure by inelastic buckling. By comparing Eq. (5.6) and Eq (5.7), which are the interaction equations used to design beam-columns for this failure mode according to the effective length approach and the notional load approach, respectively; it can be seen that the notional load approach will allow a higher design load than the effective length approach because the value of $P_{n(L)}$ is higher than $P_{n}$. The discrepancy between these two approaches is small when the value of $K_{x}$ is close to one, but as the value of $K_{x}$ increases, that is the failure mode changes toward failure by elastic buckling, the differences become apparent as can be seen by comparing the results of Figs. 5.21 and 5.23.

A beam-column designed according to the notional load approach can sometimes have higher design strength than a concentrically loaded compression member designed according to the effective length approach. That is $P_{u}$ obtained by using the notional approach can sometimes be higher than $P_{n}$. Even though this seems to be unacceptable according to the current design procedure, the finite element result from this study does support this. In the effective length approach, columns and beamcolumns subject to torsional-flexural buckling are designed based on a column curve for an equivalent pin-ended effective length member. This process of simplification
used to design members with boundary conditions other than pin-ended supports such as a rotationally restrained sway column has been shown to be conservative compared to the results obtained from performing a finite element analysis.

### 5.6.3 Cold-Formed Steel Frames

A parametric study was carried out to compare the effective length approach and the notional load approach for accuracy and appropriateness for cold-formed steel frame design. Pallet racks as shown in Fig. 5.27 were used as the vehicle for carrying out the parametric study. The parameters included: two load cases as shown in Fig. 5.26, three frame dimensions as shown in Fig. 5.27, two upright frame configurations as shown in Fig. 5.28, nine column sections as shown in Fig. 5.18, three material yield stresses $(33,55$, and 70 ksi$)$, six beam to column connection stiffnesses as given Table 5.4, and braces and shelf beams as shown in Fig. 5.29. Combinations of these parameters yielded a total of 972 pallet rack configurations for each load case. The first loading condition is the gravity load case on a frame with initial out-of plumbness of 0.5 inches in 10 feet, the second loading condition is the seismic load case on a frame with initial out-of plumbness of 0.5 inches in 10 feet, where the seismic base shear was assumed to be $12 \%$ of total gravity load on the frame.

The finite element method, which considers both geometric and material nonlinearities, was used as the basis for evaluating the accuracy of the design approaches. The finite element analysis modeling assumptions included using a threedimensional model, using open-section beam elements to model the columns and braces, using linear torsional springs to model the connection stiffness, using the

proposed base fixity equation given Chapter 2 to compute the base fixity, and using elastic-plastic material model.

The correlations between the different design approaches and the finite element results are summarized in Appendix E Tables E. 2 and E. 3 with a statistical summary of these tables given in Tables 5.5 and 5.6 where $W_{1 a}, W_{1 c}, W_{2 a}, W_{2 b}$, and $W_{2 c}$ are the ultimate load carrying capacity per bay of the frame obtained by using the Approaches $1 a, 1 c, 2 a, 2 b$, and $2 c$, respectively. $W_{\text {FEM }}$ is the ultimate load carrying capacity per bay of the frame obtained by using the finite element method. In practice, the resistance factor $\phi_{c}$ is equal to 0.85 , and $\phi_{b}$ is equal to 0.90 or 0.95 ; these values are, however, for research purposes in this study all assumed equal to one.

The results for load case 1, which are given in Appendix E Table E.2, are also plotted in Figs. 5.30 through 5.34 where the finite element analysis was used as the basis for evaluating the accuracy of the different design approaches. As can be seen in these figures, Approaches $1 c, 2 a, 2 b$, and $2 c$ are conservative compared to the finite element results while Approach $1 a$ has a few unconservative designs. The reason why these few results in Approach $1 a$ are unconservative compared to the finite element results is because the second-order effects arising from the frame story-out-plumbness was considered in the design process.

Comparison between Approach $1 c$ and $2 a$ for load case 1 indicates that $2 a$ agrees better with the finite element results than $1 c$ does. The design load obtained from the notional load approach is higher than the effective length approach because of the assumption of $K_{x}$ equal to one. This is the reason why as the value of $K_{x}$ increases the discrepancy between the design loads obtained from the effective length approach and the notional load approach also increases.

Figure 5.32 Load Case 1-Correlation between the Notional Load Approach (Approach $2 a$ ) and the FEM results

Figure 5.33 Load Case 1-Correlation between the Notional Load Approach (Approach 2b) and the FEM results

Figure 5.34 Load Case 1-Correlation between the Notional Load Approach (Approach 2c) and the FEM results

Comparisons among the three notional load approaches: $2 a, 2 b$, and $2 c$ for load case 1 indicate few differences between $2 a$ and $2 b$, and $2 c$ is more conservative than $2 a$ and $2 b$.

The results for load case 2, which are given in Appendix E Table E.3, are also plotted in Figs. 5.35 through 5.38 where the finite element analysis was used as the basis for evaluating the accuracy of the different design approaches. As can be seen in these figures, both the effective length approach and the notional load approach are conservative compared to the finite element results. The differences between the design loads obtained from the effective length approach and the notional load approach in this load case has decreased from the previous load case. The reason for this is because the horizontal force in this load case causes the storage rack to fail from the column flexural strength rather than axial strength. The column flexural strength used in both the effective length approach and the notional load approach is the same.

Comparisons between Approach $2 a$ and $2 b$ for load case 2 indicate few differences between these two approaches. Comparisons among the three notional load approaches: $2 a, 2 b$, and $2 c$, indicates that $2 c$ is slightly more conservative than $2 a$ and $2 b$ because flexural stiffness reduction is made to analysis model in Approach $2 c$.

When the notional load approach is used for an earthquake load design or wind load design, applying additional notional horizontal loads are usually not necessary if the real horizontal forces coming from the earthquake loads or the wind loads are much greater, making the additive notional horizontal loads insignificant. However, if the magnitude of the real horizontal forces coming from the earthquake loads or the wind loads are comparable with the required notional horizontal loads then that notional horizontal loads must be applied as additive loads. It is recommended that the notional horizontal loads always be applied for earthquake load design or wind load design because it is more conservative with them.

### 5.6.4 Development of Approach $2 b$

As can be seen in Fig. 5.32, the notional load approach $2 a$ is conservative compared to the finite element results, especially when the value of $K_{x}$ is close to one. Attempts are made in this study to make improvements to this approach. The objective is to increase the design load so that the results will agree better with the finite element solution. This is done by decreasing the initial out-of plumbness $\psi$ used in the second-order elastic analysis frame model. Decreasing the value of $\psi$ is equivalent to applying less notional horizontal loads, $\xi W_{\text {story }}$.

The values of $\psi$ needed to agree with finite element results were obtained by trial and error. The result was determined by linear interpolation within the tried values of $\psi$ equal to $0.0025,0.005,0.001,0.0015,0.002,0.0025,0.003,0.0035$, and 0.00417. Results are shown in Fig. 5.39. As expected the obtained value of $\psi$ decreases as the value of $K_{x}$ becomes closer to one. From this obtained relationship between $\psi$ and $K_{x}$, a new notional load approach $2 b$, which selects the notional horizontal load according to the column $K_{x}$ value, is therefore proposed, by using the following conservative design equation

$$
\psi= \begin{cases}\left(\mathrm{K}_{\mathrm{x}}-1\right) / 168, & 1<\mathrm{K}_{\mathrm{x}}<1.7  \tag{5.15}\\ 1 / 240, & \mathrm{~K}_{\mathrm{x}} \geq 1.7\end{cases}
$$

When Eq. (5.15) is used the previous result, which was shown in Fig. 5.32, improves to become as shown in Fig. 5.33. As can be seen in these figures, improvements are made when this proposed equation is used.

Figure 5.39 Load Case 1 - Frame out-of-plumb or the magnitude of the notional horizontal load required for the notional load approach

### 5.6.5 Approach $1 \boldsymbol{a}$ with $K_{x}=1.7$

Additional parametric studies were carried out using Approach $1 a$ with the value of $K_{x}$ assumed to be 1.7. The results of this parametric study carried out for the isolated rotationally restrained sway column are given in Figs. 5.40 and 5.41. The results of this parametric study carried out for the cold-formed steel frames are given in Figs. 5.42 and 5.43.

The RMI specification allows the use of $K_{x}$ equal to 1.7 as a default value. This value was chosen to give a reasonable amount of protection against sidesway for most common rack configurations. The results from this study suggested that this approach is unconservative if the real value of $K_{x}$ is much higher than 1.7. However, the results also suggested that this approach when used to design open-sections is still conservative if the real value of $K_{x}$ is just slightly higher than 1.7. The reason for this is because of the conservatism in the AISI torsional-flexural buckling provisions.

### 5.7 FINITE ELEMENT SIMULATION OF PALLET RACK TEST

A physical test of pallet rack structures and components was conducted by Peköz (1975). A finite element simulation of the physical pallet rack test was carried out to investigate the behavior of the frame and verify finite element assumptions. A pallet rack manufactured design designated as type A-LDR was studied. Its geometry is given in Appendix G and Fig. 5.44. Two load cases were studied: the first load case had gravity loads applied on each bay equally, and the second load case had a combination of gravity and horizontal loads. Horizontal loads at $1.5 \%$ of the gravity loads at each beam level were applied to the right at each beam level of the left upright frame.

Figure 5.44 Combined shell and beam finite element frame model

Figure 5.45 Middle upright frame modeled as shell elements

### 5.7.1 Beam Model

Beam elements are used to model the three-dimensional structural frame members. Available beam elements in ABAQUS that were used are the 3-node quadratic beam elements (B32) for close sections and the 3-node quadratic beam elements (B32OS) for open sections. Open section beam elements have a warping magnitude as an additional degree of freedom at each node. An idealization of the material model that is elastic-plastic with strain hardening was assumed where the yield stress and the ultimate stress were from the tensile coupon test. The material model is $F_{y}=45 \mathrm{ksi}, F_{u}=59 \mathrm{ksi}, E=29500 \mathrm{ksi}, E_{s t}=E / 45, v=0.3$, and $e_{s t}$ is 15 times the maximum elastic strain for the columns, and $F_{y}=49 \mathrm{ksi}$ and $F_{u}=59 \mathrm{ksi}$ for the beams. No tensile coupon test was conducted for the braces; therefore, its material model is assumed to be the same as the columns.

A non-linear torsional spring element was used to model the beam to column connection. The moment rotation relationship used was obtained from the physical connection test as given in Chapter 3 Table 3.1. The joint connection between the braces and column are considered to be continuous except for the warping degree of freedom.

Physical tests for determining base fixity were not available; therefore, two base fixity models were considered. One is to use a linear torsional spring model at the supports as shown in Fig. $5.15 a$ with the stiffness determined from the proposed base fixity equation given in Chapter 2. The other is to use a double axial spring model as shown in Fig. 5.15b. This model not only has the same stiffness as the first one but will also capture the upper bound limit of base fixities behavior. Further details of this base fixity model can be found in Appendix A.

A buckling analysis was first performed for the case of gravity loads to predict its critical buckling load and the corresponding buckling mode. Maximum deflection
of the buckling mode occurred at the top end of the columns as shown in Fig. 5.46. This buckling mode shape with a plumbness of 0.5 inches in 10 feet was then used as the initial geometric imperfection shape for the non-linear analysis of this load case. No plumbness was considered for the case of the combination of gravity and horizontal loads.

Non-linear finite element analyses were then performed and the results were compared with the physical tests as given in Figs. 5.48 and 5.49. When physical tests were conducted, deflection was measured at several different points. The lateral deflection of the frame measured at the bottom beam level along with its corresponding gravity load carried by the frame was used here to compare the results with the finite element approach. The finite element results designated as Model I is for the case of the base fixity modeled as the torsional spring, and Model II is for the case of the base fixity modeled as the double axial spring. However, they were not distinguished in the case of gravity loads because the same results were obtained.

### 5.7.2 Shell Model

When the results in the previous study were compared to the physical tests, it was found that two cases overestimated the load carrying capacity of the rack: one is the gravity loads and the other is the combination of gravity and horizontal loads in Model I. The results might have been due to the fact that beam elements did not accurately capture the local behavior. If this was the source of the overestimation then shell elements should be used instead. However, modeling and computation effort can become very time consuming if the entire frame is modeled by shell elements. A combined shell and beam model was instead considered in this study to investigate whether section collapses had occurred.

Figure 5.46 Finite element frame model: Critical buckling mode

Figure 5.47 Finite element shell model II Gravity + Horizontal Load Case: von Mises stress at ultimate load (5x displacement)

Figure 5.48 Results for Gravity Loads

Figure 5.49 Results for Gravity + Horizontal Loads

The bottom length of the middle column is normally the critical member in the assessment of the load carrying capacity of the pallet rack. The middle columns and their braces up to the second story beam level were; therefore, selected to be modeled by shell elements as shown in Figs. 5.44 and 5.45. It is also important that some initial local geometric imperfection is introduced in to these shell columns. Here this imperfection was introduced by superimposing the eigenmodes for the local and distortional buckling, with an imperfection magnitude of one tenth of the thickness for both modes. The boundary condition for the buckling analysis was a concentrically loaded compression column with full lateral supports to avoid overall buckling. Ends of the beam at the bottom level connecting the shell columns were also modeled as shell elements. Rigid plates were used for interconnections between the shell and beam elements. Modeling details of the shell element beam to column connection are the same as the finite simulation of the cantilever test in Charter 3. Other finite element assumptions and procedures are the same as the previous beam model. The non-linear analysis of the shell models was compared with the previous results in Figs. 5.48 and 5.49. Fig. 5.47 shows the displacement shape at the failure load for the case of the combined gravity and horizontal loads.

The new results of the two cases, the gravity loads and the combination of gravity and horizontal loads Model I, were still higher than the test results. This indicates that the local behavior in the columns was not critical in the assessment of the load carrying capacity of the rack. Although the results were not as anticipated, they were found to be in agreement with the frames' behavior in the actual test.

For the case of gravity loads in the physical test, the failure did not take place in the columns as assumed but instead took place in the beams by yielding and local buckling. Shell elements should have been used for modeling the shelf beams. However, further finite element analysis was not needed because the load carrying
capacity of the tested frame was consistent with the load carrying capacity of the tested simply supported shelf beam. This comparison could be made because although the beam to column connections was semi-rigid they were rather flexible. Therefore the results of the simply supported shelf beam could be used to approximate the frame capacity.

For the case of the combination of gravity and horizontal loads in the physical test, failure was due to sidesway collapse where most of the lag bolts were broken off due to the excessive rotation of the columns at the bases. This result falls in line between the finite element Model I and Model II as seen in Fig. 5.49. For finite element Model II failure took place by exceeding the upper bound limit of the base fixity, which means that the actual upper bound limit of the base fixity was slightly higher than assumed. Additional resistance from the base fixity could be due to the presence of the lag bolts.

### 5.8 CONCLUSIONS

Numerous frame elastic buckling analyses were carried out to evaluate the alignment chart and the AISI torsional-flexural buckling provisions. It was found that the alignment chart is inaccurate when used for semi-rigid frames, and the differences between the base fixity and the connection flexibility is high, the results are unconservative when used for the bottom story column and too conservative when used for the second story column. Results showed that the elastic buckling load obtained from the AISI torsional-flexural buckling provisions is generally conservative compared the results obtained from performing frame elastic buckling analysis.

A study comparing the effective length approach and the notional load approach for cold-formed steel frame and beam-column design was also carried out. The finite element method, which considers both geometric and material nonlinearities, was used as the basis for evaluating the accuracy of these two design approaches. Results showed that, the effective length approach is more conservative than the notional load approach, and that the notional load approach agrees with the finite element results better than the effective length approach does. It is therefore recommended that the notional load approach, in particularly Approach $2 c$, be considered as an alternative means for cold-formed steel frame and beam-column design. In Approach $2 c$ the notional load parameter $\xi$ is assumed equal to $1 / 240$ and the second-order elastic analysis is performed on a reduced flexural stiffness model. A $10 \%$ reduction in the flexural stiffness is proposed.

## Chapter

## Results and Conclusions

The objective of this research was to make improvements in the RMI (1997) Specification and the AISI (1996) Specification. The results have indicated that improvements in these current design procedures are possible. The following summarizes the results and conclusions. The symbol * indicates recommendations for changes in the specifications.

* 1. It was found that the current RMI base fixity equation underestimates the stiffness of the column base. Several analytical models of the column base were studied. The base fixity was found by solving a normal load on the boundary of the half-space problem. With this approach a parametric study was carried out for a wide range of column base configurations to develop a new base fixity equation. Unless actual tests are conducted to obtain the base fixity, the proposed base fixity equation, Eq. (2.12), along with its upper bound limit of the usage of this equation, Eq. (2.17), is recommended. Finite element studies were used to verify this proposed equation. The proposed equation agrees well with the finite element results.
*2. A new beam to column connection test was developed to be used instead of the cantilever test. The actual frames shear to moment ratio is better represented in this proposed portal test than the current cantilever test. Therefore it is recommended that in addition to current beam to column connection tests, this proposed portal test, which is given Chapter 3, should be included as a possible means of determining the moment to rotation relationship of the connection.
*3. Numerous finite element elastic buckling analyses of perforated members were carried out. Results indicate that increasing the presence of perforations in the section will reduce the buckling strength. To take this into account, instead of using the unperforated section properties to predict the buckling strength of perforated sections, as assumed in the current design specification, it is recommend that better results can be obtained by using the weighted section, or the average section properties for torsional-flexural buckling, the average section properties for lateral buckling, and the net moment of inertia section properties for flexural buckling.

4. The torsional-flexural buckling equation used in the current design provision was evaluated by comparing the results with finite element solutions. It was found that the elastic buckling load obtained from using the buckling equation is usually conservative compared to the finite element results.
5. Effective length factors used in the current design provision were evaluated by comparing the results with finite element solutions. It was found that the recommended value of $K_{y}$ taken as one is in general conservative while $K_{t}$ taken as 0.8 is in most cases reasonable, providing that the upright frame has adequate braces and the column base is constrained against twisting.
*6. Finite element simulations of stub-column tests were carried out to evaluate the current effective design area equation and effective section modulus equation. Modifications to these equations are suggested. The effective design area
equation of the RMI specification, Eq. (4.1), should be modified to the proposed equation, Eq. (4.5). The effective section modulus equation of the RMI specification, Eq. (4.7), should be modified to the proposed equation, Eq. (4.8).
6. Unperforated and perforated member strength capacity, under different loading conditions and for various member lengths, was computed using the finite element method and compared to those values using the RMI specification, which uses Eqs. (4.1) and (4.7), and the proposed design approach, which uses Eqs. (4.5) and (4.8). It was found that the compressive axial strength and the beam-columns strength designed according to the proposed design approach agrees better to the finite element results than the current design procedure does. Flexural strength design according to either design approach is quite conservative compared to the finite element results, if distortional buckling failure mode does not take place.
7. Finite element simulation of stub-column tests under bending moments were carried out to evaluate the current RMI procedures for determining the member flexural strength. It was found that current procedures for calculating the nominal flexural strength on the basis of initiation of yielding $M_{n}$ for members not subject to lateral buckling is conservative, especially for weak axis bending. Equations for determining the nominal flexural strength on the basis of inelastic reserve capacity $M_{p}$ are given in this study and have been shown to agree better with the finite element results than $M_{n}$ does.
8. Equations for determining the maximum bending moments in elastic beamcolumns for the case where it is simply supported with equal end eccentricities and failure is by torsional-flexural buckling are given. Determining the maximum moments for this boundary condition using the current moment magnification factor suggested by the AISI specification has been shown to give unconservative results if the member failure is by torsional-flexural.
9. Numerous frame elastic buckling analyses were carried out to evaluate the alignment chart. It was found that the alignment chart is inaccurate when used for semi-rigid frames, and the differences between the base fixity and the connection flexibility is high. The results are unconservative when used for the bottom story column and too conservative when used for the second story column.
*11. A study comparing the effective length approach and the notional load approach for cold-formed steel frame and beam-column design was also carried out. The finite element method, which considers both geometric and material nonlinearities, was used as the basis for evaluating the accuracy of these two design approaches. Results show that, the effective length approach is more conservative than the notional load approach, and that the notional load approach agrees better with the finite element results than the effective length approach does. It is therefore recommended that the notional load approach, in particularly Approach $2 c$, be considered as an alternative means for cold-formed steel frame and beam-column design. The following is the recommended notional load approach design procedure:

Storage rack columns are considered to be subject to a combined compressive axial load and bending. The axial compression strength $P_{u}$ and flexural strength $M_{u}$ of the column is determined according to following interaction equation:

$$
\begin{equation*}
\frac{P_{u}}{\phi_{c} P_{n(L)}}+\frac{M_{u}}{\phi_{b} M_{n}} \leq 1 \tag{6.1}
\end{equation*}
$$

where $P_{n(L)}$ is the axial strength computed based on the values of $K_{x}$ and $K_{y}$ both assumed equal to one, and $K_{t}$ assumed equal to 0.8 . The relationship between $P_{u}$ and $M_{u}$ is obtained by performing a second-order elastic analysis, or alternatively approximated by performing a first-order elastic analysis and using moment magnification factors. The analysis is conducted on a geometrically perfect frame subject to notional horizontal load $\xi W_{\text {story }}$ at each story, where $W_{\text {story }}$ is the gravity
load at that story, and $\xi$ is the notional load parameter equal to $1 / 240$. The notional horizontal load is determined from factored design loads, and is applied as an additive force to the real horizontal forces coming from the seismic load or wind load, to cause maximum frame instability. A 10\% reduced flexural stiffness analysis model is used. This can be done by using a reduced flexural stiffness $E I *$ for all members and connections in the analysis model

$$
\begin{equation*}
E I^{*}=0.9 E I \tag{6.2}
\end{equation*}
$$

where $E$ is the modulus of elasticity, and $I$ is the moment of inertia about the axis of bending.

# Appendix A 

## Column Bases

## A. 1 CONCRETE SPRINGS

From Fig. 2.2 vertical displacements are related to the base rotation as

$$
u_{2}=-\theta x_{1}
$$

with the spring reaction

$$
\sigma_{22}=k u_{2}
$$

the resisting moment could be found by integrating over the area of the base plate

$$
\begin{gathered}
M=-\int_{A} x_{1} \sigma_{22} d A \\
M=\theta k b \int_{-d / 2}^{d / 2} x_{1}^{2} d x_{1}=\frac{\theta k b d^{3}}{12}
\end{gathered}
$$

from this last equation the base fixity can be obtained as

$$
\frac{M}{\theta}=\frac{k b d^{3}}{12}
$$

if the stiffness of these springs are set to

$$
k=\frac{E}{d}
$$

where $E$ is the modulus of elasticity of the floor. For this case and all following models the floor is assumed to be concrete, $E=E_{c}$. The base fixity is found to be the same as in Eq. (2.1).

## A. 2 CONCRETE BEAM

Recall from the beam theory that the normal stress can be written as

$$
\sigma_{22}=-\frac{M x_{1}}{I}
$$

From Hooke's law this equation gives

$$
\varepsilon_{22}=-\frac{M x_{1}}{E I}
$$

From Fig. 2.3 the radius of curvature and the strain are related as follows:

$$
\theta=\frac{\alpha}{\rho}=-\frac{\varepsilon_{22} \alpha}{x_{1}}
$$

From these last two equations the base fixity can found as

$$
\frac{M}{\theta}=\frac{E I}{\alpha}
$$

where

$$
I=\frac{b d^{3}}{12}
$$

If the depth of the concrete block under the base plate is assumed to be

$$
\alpha=d
$$

the base fixity is found to be the same as in Eq. (2.1).

## A. 3 CONCRETE BLOCK

Define the stress field in the concrete block under the base plate as

$$
\begin{gathered}
\sigma_{22}=-k x_{1} \\
\sigma_{i j}=0
\end{gathered}
$$

From Hooke's law the strain field can be found as

$$
\begin{gathered}
\varepsilon_{i j}=\frac{(1+v)}{E} \sigma_{i j}-\frac{v}{E} \sigma_{k k} \delta_{i j} \\
\varepsilon_{22}=-\frac{k x_{1}}{E} \\
\varepsilon_{11}=\varepsilon_{33}=\frac{v k x_{1}}{E} \\
\varepsilon_{12}=\varepsilon_{13}=\varepsilon_{23}=0
\end{gathered}
$$

By definition the displacement field is related to the stain field as

$$
\varepsilon_{i j}=\frac{1}{2}\left(u_{i, j}+u_{j, i}\right)
$$

Integration of the stain field equations gives the displacement field as

$$
\begin{gathered}
u_{1}=\frac{k}{2 E}\left(\left(x_{2}-\alpha\right)^{2}+v\left(x_{1}^{2}-x_{3}^{2}\right)\right) \\
u_{2}=-\frac{k x_{1}\left(x_{2}-\alpha\right)}{E} \\
u_{3}=\frac{v k x_{1} x_{3}}{E}
\end{gathered}
$$

Plot of the displacement field is shown in Fig. 2.4. The resisting moment could be found by integrating over the area of the base plate

$$
\begin{gathered}
M=-\int_{A} x_{1} \sigma_{22} d A \\
M=k b \int_{-d / 2}^{d / 2} x_{1}^{2} d x_{1}=\frac{k b d^{3}}{12}
\end{gathered}
$$

with the known vertical displacement, the rotation at the top of the concrete block $x_{2}=0$ is

$$
\theta=\frac{u_{2}}{x_{1}}=\frac{k \alpha}{E}
$$

From these last two equations the base fixity can found as

$$
\frac{M}{\theta}=\frac{b d^{3} E}{12 \alpha}
$$

Similar to Model 2 by setting the depth of the concrete block under the base plate as

$$
\alpha=d
$$

the base fixity is found to be the same as in Eq. (2.1).

## A. 4 TWO-DIMENSIONAL ELASTOSTATIC PROBLEM: NORMAL LOADS ON THE BOUNDARY OF HALF-SPACE

The stress function for Fig. 2.5a where the load extends indefinitely to the left is given in Timoshenko and Goodier (1969) as follows:

$$
\phi_{1}\left(p, x_{1}, x_{2}\right)=-\frac{p}{2 \pi}\left(\left(x_{1}^{2}+x_{2}^{2}\right) \tan ^{-1} \frac{x_{2}}{x_{1}}-x_{1} x_{2}\right)
$$

where the stress field could be found by differentiating the stress function as

$$
\sigma_{11}=\phi_{1,22} \quad \sigma_{22}=\phi_{1,11} \quad \sigma_{12}=-\phi_{1,12}
$$

the results of which are

$$
\begin{gathered}
\sigma_{11}=-\frac{p}{\pi}\left(\tan ^{-1} \frac{x_{2}}{x_{1}}+\frac{x_{1} x_{2}}{x_{1}^{2}+x_{2}^{2}}\right) \\
\sigma_{22}=-\frac{p}{\pi}\left(\tan ^{-1} \frac{x_{2}}{x_{1}}-\frac{x_{1} x_{2}}{x_{1}^{2}+x_{2}^{2}}\right) \\
\sigma_{12}=-\frac{p x_{2}^{2}}{\pi\left(x_{1}^{2}+x_{2}^{2}\right)}
\end{gathered}
$$

From Hooke's law and assuming the problem to be plane strain the, strain field could be obtained. By integration of the strain field the displacement field is found as

$$
\begin{gathered}
u_{1}=-\frac{p(1+v)}{\pi E}\left((1-2 v) x_{1} \tan ^{-1} \frac{x_{2}}{x_{1}}+(1-v) x_{2} \ln \left(x_{1}^{2}+x_{2}^{2}\right)+x_{2}\right) \\
u_{2}=-\frac{p(1+v)}{\pi E}\left((1-2 v) x_{2} \tan ^{-1} \frac{x_{2}}{x_{1}}-(1-v) x_{1} \ln \left(x_{1}^{2}+x_{2}^{2}\right)\right)
\end{gathered}
$$

Similar to the previous problem, the stress function for Fig. $2.5 b$ where the linearly increasing load extending indefinitely to the left is given in Timoshenko and Goodier (1969) as follows:

$$
\phi_{2}\left(p, x_{1}, x_{2}, d\right)=\frac{p}{6 \pi d}\left(\left(x_{1}^{3}+3 x_{1} x_{2}^{2}\right) \tan ^{-1} \frac{x_{2}}{x_{1}}+x_{2}^{3} \ln \left(x_{1}^{2}+x_{2}^{2}\right)-x_{1}^{2} x_{2}\right)
$$

where the stress field could be found by differentiating the stress function as

$$
\sigma_{11}=\phi_{1,22} \quad \sigma_{22}=\phi_{1,11} \quad \sigma_{12}=-\phi_{1,12}
$$

the results of which are

$$
\sigma_{11}=\frac{p}{\pi d}\left(x_{1} \tan ^{-1} \frac{x_{2}}{x_{1}}+x_{2} \ln \left(x_{1}^{2}+x_{2}^{2}\right)+\frac{5 x_{2}}{3}\right)
$$

$$
\begin{gathered}
\sigma_{22}=\frac{p}{\pi d}\left(x_{1} \tan ^{-1} \frac{x_{2}}{x_{1}}-x_{2}\right) \\
\sigma_{12}=-\frac{p x_{2}}{\pi d} \tan ^{-1} \frac{x_{2}}{x_{1}}
\end{gathered}
$$

From Hooke's law and assuming the problem to be plane strain the strain field could be obtained. By integration of the strain field the displacement field is found as

$$
\begin{aligned}
u_{1}= & \frac{p(1+v)}{\pi d E}\left(\left(\frac{(1-2 v)\left(x_{1}^{2}-x_{2}^{2}\right)}{2}-x_{2}^{2}\right) \tan ^{-1} \frac{x_{2}}{x_{1}}+(1-v) x_{1} x_{2} \ln \left(x_{1}^{2}+x_{2}^{2}\right)\right. \\
& \left.+\frac{(1+2 v) x_{1} x_{2}}{6}\right) \\
u_{2}= & \frac{p(1+v)}{\pi d E}\left((1-2 v) x_{1} x_{2} \tan ^{-1} \frac{x_{2}}{x_{1}}-\frac{\left(x_{1}^{2}-v\left(x_{1}^{2}-x_{2}^{2}\right)\right)}{2} \ln \left(x_{1}^{2}+x_{2}^{2}\right)\right. \\
& \left.+\frac{(1-v)\left(x_{1}^{2}-x_{2}^{2}\right)}{6}-\frac{x_{2}^{2}}{3}\right)
\end{aligned}
$$

The stress function for the Fig. 2.5c problem may be found by superposition the stress function for Fig. $2.5 a$ and $2.5 b$ as

$$
\phi=\phi_{1}\left(q, x_{1}, x_{2}\right)+\phi_{1}\left(q, x_{1}+d, x_{2}\right)+\phi_{2}\left(-2 q, x_{1}, x_{2}, d\right)+\phi_{2}\left(2 q, x_{1}+d, x_{2}, d\right)
$$

the stress field could then be found by differentiating this new stress function or by similar superposition of the stress field of Fig. $2.5 a$ and $2.5 b$. Normal stress on the boundary $x_{2}=0$ between $x_{1}=0$ and $x_{1}=d$ is found to be

$$
\sigma_{22}=-\frac{q\left(2 x_{1}+d\right)}{d}
$$

which is a linear bending stress under the base plate. The resisting moment could be found by integrating over the area of the base plate

$$
\begin{gathered}
M=-\int_{A} x_{1} \sigma_{22} d A \\
M=\frac{q}{d} \int_{-d}^{0}\left(2 x_{1}+d\right) x_{1} d x_{1}=\frac{q d^{2}}{6}
\end{gathered}
$$

Displacement field could either be found from Hooke's law and assuming the problem to be plane strain or by superposition of the resulting displacement field of Fig. 2.5a and $2.5 b$. The vertical displacement, $u_{2}\left(x_{1}, x_{2}\right)$ on the boundary $x_{2}=0$ between $x_{1}=0$ and $x_{1}=d$ is found and plotted in Fig. 2.6

$$
u_{2}\left(x_{1}, 0\right)=\frac{q\left(1-v^{2}\right)}{d \pi E}\left(x_{1}\left(x_{1}+d\right) \ln \left(\frac{x_{1}^{2}}{\left(x_{1}+d\right)^{2}}\right)+\frac{d}{3}\left(2 x_{1}+d\right)\right)
$$

at the edge of the base plate the displacement is

$$
u_{2}(0,0)=\frac{q\left(1-v^{2}\right) d}{3 \pi E}
$$

the dashed line in Fig. 2.6 is used as an approximate rotation of the base plate

$$
\theta=\frac{2 u_{2}(0,0)}{d}=\frac{2 q\left(1-v^{2}\right)}{3 \pi E}
$$

Dividing the resisting moment with this last equation, the base fixity equation is obtained

$$
\frac{M}{\theta}=\frac{d^{2} \pi E}{4\left(1-v^{2}\right)}
$$

## A. 5 THREE-DIMENSIONAL ELASTOSTATIC PROBLEM: NORMAL LOADS ON THE BOUNDARY OF HALF-SPACE

The displacement field for the Boussinesq problem of concentrated normal force on boundary of half-space is as follows:

$$
\begin{gathered}
u_{\alpha}=\frac{P}{4 \pi G}\left(\frac{x_{3} x_{\alpha}}{r^{3}}-\frac{x_{\alpha}(1-2 v)}{r\left(r+x_{3}\right)}\right) \\
u_{3}=\frac{P}{4 \pi G}\left(\frac{x_{3}^{2}}{r^{3}}+\frac{2(1-v)}{r}\right)
\end{gathered}
$$

where

$$
G=\frac{E}{2(1+v)} \quad \text { and } \quad r=\sqrt{x_{1}^{2}+x_{2}^{2}+x_{3}^{2}}
$$

As shown in Sokolnikoff (1983) the solution can be generalized for distribution of normal loads. Let $p(\xi, \eta)$ be the distributed normal load at coordinate $(\xi, \eta)$ on the boundary. Inserting this in the previous equations and integrating over the boundary plane the generalized equation is obtained as

$$
\begin{gathered}
u_{\alpha}=\frac{1}{4 \pi G}\left(x_{3} x_{\alpha} \iint_{A} \frac{p(\xi, \eta)}{r^{3}} d \xi d \eta-x_{\alpha}(1-2 v) \iint_{A} \frac{p(\xi, \eta)}{r\left(r+x_{3}\right)} d \xi d \eta\right) \\
u_{3}=\frac{1}{4 \pi G}\left(x_{3}^{2} \iint_{A} \frac{p(\xi, \eta)}{r^{3}} d \xi d \eta+2(1-v) \iint_{A} \frac{p(\xi, \eta)}{r} d \xi d \eta\right)
\end{gathered}
$$

where

$$
r=\sqrt{\left(x_{1}-\xi\right)^{2}+\left(x_{2}-\eta\right)^{2}+x_{3}^{2}}
$$

For the case of a linear bending stress the distribution is given as

$$
p(\xi, \eta)=\frac{M \xi}{I}
$$

where

$$
I=\frac{b d^{3}}{12}
$$

Consider a square plate of a unit width, $d=b=1$ with a unit moment applied, $M=1$. The vertical displacement $u_{3}\left(x_{1}, x_{2}, x_{3}\right)$ is found at the center edge of the plate and $d / 64$ away from the boundary to avoid singularity from the numerical integration

$$
u_{3}\left(\frac{d}{2}, 0, \frac{d}{64}\right)=\frac{7.746}{4 \pi G}
$$

where it is used to find an approximate rotation of the base plate

$$
\theta=\frac{2 u_{3}\left(\frac{d}{2}, 0, \frac{d}{64}\right)}{d}=\frac{7.746(1+v)}{\pi E}
$$

thus the base fixity can be found as

$$
\frac{M}{\theta}=\frac{\pi E}{7.746(1+v)}
$$

The result is found to be higher then Eq. (2.1) by a factor of

$$
\frac{12 \pi}{7.746(1+v) b d^{2}}=4.05
$$

Similar to the square plate problem, consider a rectangular plate, $d=2 b=1$ with a unit moment applied, $M=1$. The vertical displacement $u_{3}\left(x_{1}, x_{2}, x_{3}\right)$ is found at the center edge of the plate and $d / 64$ away from the boundary to avoid singularity from the numerical integration

$$
u_{2}\left(\frac{d}{2}, 0, \frac{d}{64}\right)=\frac{12.253}{4 \pi G}
$$

where it is used to find an approximate rotation of the base plate

$$
\theta=\frac{2 u_{2}\left(\frac{d}{2}, \frac{d}{64}\right)}{d}=\frac{12.253(1+v)}{\pi E}
$$

thus the base fixity can be found as

$$
\frac{M}{\theta}=\frac{\pi E}{12.253(1+v)}
$$

The result is found to be higher than Eq. (2.1) by a factor of

$$
\frac{12 \pi}{12.253(1+v) b d^{2}}=5.128
$$

## A. 6 DOUBLE AXIAL SPRING

The double axial spring model shown in Fig. $5.15 b$ is used to model the base fixity in the frame analysis. Unlike the simple torsional spring model shown in Fig. 5.15a the double axial spring model can capture the upper bound limit of base fixities behavior. The resistant moment $M$ developed from the double axial spring model shown in Fig. $5.15 c$ is

$$
M=k_{s} \delta_{2} \Delta
$$

For small deformations, the angle of rotation $\theta$ can be approximated as

$$
\theta=\frac{2 \delta_{2}}{\Delta}
$$

The axial spring stiffness $k_{s}$ can then be computed from these last two equations as

$$
k_{s}=\frac{2 M}{\Delta^{2} \theta}
$$

Recall Eq. (2.16) the upper bound limit for the base fixity equation is given as

$$
\frac{M}{P}=\frac{S}{A}
$$

Let the resistant moment $M$ and total reaction force $P$ be from the double axial spring model shown in Fig. $5.15 c$ then this last equation becomes

$$
\frac{k_{s} \delta_{2} \Delta}{2 k_{s} \delta_{1}}=\frac{S}{A}
$$

The upper bound limit is reached when the left spring is completely unloaded ( $\delta_{1}=\delta_{2}$ ) and all the force is transferred to the right spring as shown in Fig. 5.15d. Imposing this condition the springs moment arm, $\Delta$ can then computed from the last equation as

$$
\Delta=\frac{2 S}{A}
$$

## C. 1 ELASTIC BUCKLING OF COMPRESSION MEMBERS UNDER ECCENTRIC LOAD

The elastic buckling loads can be computed by solving the following cubic equation:

$$
c_{1} P_{e}^{3}+c_{2} P_{e}^{2}+c_{3} P_{e}+c_{4}=0
$$

The lowest positive elastic buckling load is the governing critical compression load.

$$
P_{e}=\min \left(P_{e 1}, P_{e 2}, P_{e 3}\right)
$$

where

$$
\begin{gathered}
c_{1}=a_{x}^{2}+a_{y}^{2}-\bar{r}_{o}^{2} \\
c_{2}=\bar{r}_{o}^{2}\left(P_{e x}+P_{e y}+P_{e t}\right)-P_{e x} a_{y}^{2}-P_{e y} a_{x}^{2} \\
c_{3}=-\bar{r}_{o}^{2}\left(P_{e x} P_{e y}+P_{e x} P_{e t}+P_{e y} P_{e t}\right) \\
c_{4}=\bar{r}_{o}^{2} P_{e x} P_{e y} P_{e t}
\end{gathered}
$$

$$
\begin{gathered}
P_{e x}=\frac{\pi^{2} \mathrm{EI}_{x}}{\left(K_{x} L_{x}\right)^{2}} \\
P_{e y}=\frac{\pi^{2} \mathrm{EI}_{y}}{\left(K_{y} L_{y}\right)^{2}} \\
P_{e t}=\frac{1}{r_{o b}^{2}}\left(G J+\frac{\pi^{2} \mathrm{EC}_{w}}{\left(K_{t} L_{t}\right)^{2}}\right) \\
a_{x}=x_{o}-e_{x} \\
r_{y}^{2}=y_{x}^{2}+r_{y}^{2}+e_{y}^{2}+y_{o}^{2} \\
\bar{r}_{o}^{2}=r_{o}^{2}+\beta_{x} e_{y}+\beta_{y} e_{x} \\
\beta_{x}=\frac{1}{\mathrm{I}_{x}} \int_{\mathrm{A}} y\left(x^{2}+y^{2}\right) d A-2 y_{o} \\
\beta_{y}=\frac{1}{\mathrm{I}_{y}} \int_{\mathrm{A}} x\left(x^{2}+y^{2}\right) d A-2 x_{o}
\end{gathered}
$$

and
$P_{e 1}, P_{e 2}$ and $P_{e 3}=$ roots of the cubic equation.
$E=$ Modulus of elasticity
$G=$ Shear modulus
$J=$ St. Venant torsion constant of cross section
$C_{w}=$ Torsional warping constant of cross section
$K L=$ Effective length of compression member
$I_{x}=$ Moment of inertia about the x -axis
$I_{y}=$ Moment of inertia about the y -axis
$r_{x}=$ Radius of gyration of cross section about the x -axis
$r_{y}=$ Radius of gyration of cross section about the $y$-axis
$x_{o}=\mathrm{x}$-coordinate of the shear center
$y_{o}=\mathrm{y}$-coordinate of the shear center
$e_{x}=$ Eccentricity about the x-axis
$e_{y}=$ Eccentricity about the y-axis
$x$ - and $y$-axis $=$ Centroidal principal axes
If the load acts along the shear center axis $\left(e_{x}=x_{o}, e_{y}=y_{o}\right)$ we have

$$
\begin{aligned}
& P_{e 1}=P_{e x} \\
& P_{e 2}=P_{e y} \\
& P_{e 3}=P_{e t}
\end{aligned}
$$

If the load acts along the shear center $y$-axis $\left(e_{x}=x_{o}\right)$ we have

$$
\begin{gathered}
P_{e 1, e 2}=\frac{1}{2 \beta}\left(\left(P_{e y}+P_{e t}\right) \pm \sqrt{\left(P_{e y}+P_{e t}\right)^{2}-4 \beta P_{e y} P_{e t}}\right) \\
P_{e 3}=P_{e x} \\
\beta=1-\left(\frac{a_{y}}{\bar{r}_{o}}\right)^{2}
\end{gathered}
$$

where

If the load acts along the shear center $x$-axis $\left(e_{y}=y_{o}\right)$ we have

$$
\begin{gathered}
P_{e 1, e 2}=\frac{1}{2 \beta}\left(\left(P_{e x}+P_{e t}\right) \pm \sqrt{\left(P_{e x}+P_{e t}\right)^{2}-4 \beta P_{e x} P_{e t}}\right) \\
P_{e 3}=P_{e y}
\end{gathered}
$$

where

$$
\beta=1-\left(\frac{a_{x}}{\bar{r}_{o}}\right)^{2}
$$

## C. 2 ELASTIC LATERAL BUCKLING OF FLEXURAL MEMBERS UNDER BIAXIAL BENDING

The elastic lateral buckling loads can be computed by solving the following equation:

$$
M_{e y 1, e y 2}=-\frac{1}{2\left(c^{2} / P_{e y}+1 / P_{e x}\right)}\left(\left(\beta_{x} c+\beta_{y}\right) \pm \sqrt{\left(\beta_{x} c+\beta_{y}\right)^{2}+4 r_{o}^{2} P_{e t}\left(c^{2} / P_{e y}+1 / P_{e x}\right)}\right)
$$

The lowest positive lateral elastic buckling load is the governing critical load.

$$
M_{e y}=\min \left(M_{e y 1}, M_{e y 2}\right)
$$

where $c=M_{e x} / M_{e y}$ is the defined moment ratio.

## C. 3 ELASTIC LATERAL BUCKLING OF FLEXURAL MEMBERS BENDING ABOUT THE $\boldsymbol{y}$-axis

The elastic lateral buckling loads can be computed by solving the following equation:

$$
M_{e y 1, e y 2}=-\frac{P_{e x}}{2}\left(\beta_{y} \pm \sqrt{\beta_{y}^{2}+4 r_{o}^{2}\left(P_{e t} / P_{e x}\right)}\right)
$$

The lowest positive lateral elastic buckling load is the governing critical load.

$$
M_{e y}=\min \left(M_{e y 1}, M_{e y 2}\right)
$$

## C. 4 ELASTIC LATERAL BUCKLING OF FLEXURAL MEMBERS BENDING ABOUT THE $\boldsymbol{x}$-axis

The elastic lateral buckling loads can be computed by solving the following equation:

$$
M_{e x 1, e x 2}=-\frac{P_{e y}}{2}\left(\beta_{x} \pm \sqrt{\beta_{x}^{2}+4 r_{o}^{2}\left(P_{e t} / P_{e y}\right)}\right)
$$

The lowest positive lateral elastic buckling load is the governing critical load.

$$
M_{e x}=\min \left(M_{e x 1}, M_{e x 2}\right)
$$

## Appendix

## D

## Beam-Columns

Peköz and Celebi (1969) presented an approximate analysis approach for elastic beamcolumns with equal end eccentricities. For the simply supported case, the functions for deflections were assumed to satisfy the geometric boundary conditions and have the forms.

$$
\begin{gathered}
u=\frac{P e_{x}}{2 E I_{y}} z(z-L)+A_{0} \sin \frac{\pi z}{L} \\
v=\frac{P e_{y}}{2 E I_{x}} z(z-L)+B_{0} \sin \frac{\pi z}{L} \\
\phi=C_{0} \sin \frac{\pi z}{L}
\end{gathered}
$$

These deflection functions are then used in the elastic beam-column differential equations where the unknown coefficients $A_{0}, B_{0}$, and $C_{0}$ are solved by applying the Galerkin method.

$$
\begin{gathered}
A_{0}=\frac{P^{2}}{\Delta P_{e y}}\left\{P a_{x}\left(P e_{x} a_{x}+P_{e y} e_{y} a_{y}\right)-e_{x}\left(P_{e x}-P\right)\left[\left(P_{e t}-P\right) \bar{r}_{0}^{2}+P a_{y}^{2}\right]\right\} \\
B_{0}=\frac{P^{2}}{\Delta P_{e x}}\left\{P a_{y}\left(P e_{y} a_{y}+P_{e x} e_{x} a_{x}\right)-e_{y}\left(P_{e y}-P\right)\left[\left(P_{e t}-P\right) \bar{r}_{0}^{2}+P a_{x}^{2}\right]\right\} \\
C_{0}=\frac{P^{2}}{\Delta}\left[\left(P_{e y}-P\right) e_{y} a_{x}-\left(P_{e x}-P\right) e_{x} a_{y}\right]
\end{gathered}
$$

where

$$
\Delta=\frac{\pi}{4}\left|\begin{array}{ccc}
P_{e y}-P & 0 & -P a_{y} \\
0 & P_{e x}-P & P a_{x} \\
-P a_{y} & P a_{x} & \bar{r}_{0}^{2}\left(P_{e t}-P\right)
\end{array}\right|
$$

and $P$ is the applied eccentric load. Definitions of the other variables are given in the Appendix C. Inserting the solved deformation functions in the basic beam equations

$$
\begin{gathered}
M_{x}=E I_{x} \frac{d^{2} v}{d z^{2}} \\
M_{y}=E I_{y} \frac{d^{2} u}{d z^{2}} \\
M_{t}=G J \frac{d \phi}{d z}-E C_{w} \frac{d^{3} \phi}{d z^{3}}
\end{gathered}
$$

The corresponding bending moments about principal axes and twisting moment in the beam-columns are obtained as follows:

$$
\begin{aligned}
& M_{x}=P e_{y}-B_{0} P_{e x} \sin \frac{\pi z}{L} \\
& M_{y}=P e_{x}-A_{0} P_{e y} \sin \frac{\pi z}{L}
\end{aligned}
$$

$$
M_{t}=C_{0}\left(\frac{\pi G J}{L}+\frac{\pi^{3} E C_{w}}{L^{3}}\right) \cos \frac{\pi z}{L}
$$

The maximum values of these moments are given in Eq. (4.13) to (4.15)

## ${ }_{\text {Appendix }}^{\boldsymbol{F}}$

## Design Examples

## DESIGN EXAMPLE - Rotationally Restrained Sway Column

Given:

1. Section C9 as shown in Fig 5.18. The section properties are: $A=1.2$ in. ${ }^{2}$, $I_{x}=1.8 \mathrm{in} .^{4}, S_{x}=1.161 \mathrm{in} .{ }^{4}, F_{y}=55 \mathrm{ksi}$, and $Q=1$
2. Rotationally restrained sway column as shown in Fig. 5.17a, with $L=60$ in., $\psi=1 / 240, G_{A}=0.6, G_{B}=20$, and $K_{x}=1.965$
3. For research purposes assume $\phi_{c}=1$ and $\phi_{b}=1$

Required:

1. Determined the axial load carrying capacity of the column based on Chapter 5 Approaches $1 a, 1 c, 2 a, 2 b$, and $2 c$
2. Compare the results with the finite element solution $P_{\text {FEM }}=30.64 \mathrm{kips}$

## APPROACH 1 - EFFECTIVE LENGTH APPROACH

Approach 1a-Concentrically Loaded Compression Members

$$
\begin{aligned}
& P_{e x}=\frac{\pi^{2} E I_{x}}{\left(K_{x} L_{x}\right)^{2}}=\frac{\pi^{2}(29500)(1.8)}{((1.965)(60))^{2}}=37.7 \mathrm{kips} \\
& F_{e}=\frac{P_{e x}}{A}=\frac{37.7}{1.2}=31.42 \mathrm{ksi} \\
& \lambda_{c}=\sqrt{\frac{F_{y}}{F_{e}}}=\sqrt{\frac{55}{31.42}}=1.32<1.5, \text { therefore } \\
& F_{n}=\left(0.658^{\lambda_{c}^{2}}\right) F_{y}=\left(0.658^{1.32^{2}}\right)(55)=26.52 \mathrm{ksi} \\
& P_{n}=A_{e} F_{n}=(1.2)(26.52)=31.82 \mathrm{kips} \quad \text { (Fully effective) } \\
& P_{u}=\phi_{c} P_{n}=(1)(31.82)=31.82 \mathrm{kips} \quad \text { Answer }
\end{aligned}
$$

## Approach 1c-Combined Compressive Axial Load and Bending

a) The objective is to solve the following interaction equation for $P_{u}$

$$
\frac{P_{u}}{\phi_{c} P_{n}}+\frac{M_{u}}{\phi_{b} M_{n}}=1
$$

b) Approximate $M_{u}$ by modifying $M_{l t}$, which is the moment from first-order elastic analysis, using moment magnifier

$$
M_{u}=\frac{C_{m x} M_{l t}}{\left(1-\frac{P_{u}}{P_{e x}}\right)}
$$

c) Express the relationship between $P_{u}$ and $M_{l t}$ from first-order elastic analysis as

$$
M_{l t}=C_{l x} P_{u}
$$

where

$$
\begin{aligned}
& C_{l x}=\frac{\xi L \bar{\alpha}_{A}\left(2+\bar{\alpha}_{B}\right)}{2\left(\bar{\alpha}_{A}+\bar{\alpha}_{A} \bar{\alpha}_{B}+\bar{\alpha}_{B}\right)} \\
& \xi=\psi=\frac{1}{240} \\
& \bar{\alpha}_{A}=\frac{6}{G_{A}}=\frac{6}{0.6}=10 \\
& \bar{\alpha}_{B}=\frac{6}{G_{B}}=\frac{6}{20}=0.3
\end{aligned}
$$

therefore

$$
C_{l x}=\frac{(1 / 240)(60)(10)(2+0.3)}{2(10+(10)(0.3)+0.3)}=0.216
$$

d) Using the equations given in (b) and (c), the interaction equation given in (a) becomes

$$
\frac{P_{u}}{\phi_{c} P_{n}}+\frac{C_{m x} C_{l x} P_{u}}{\phi_{b} M_{n}\left(1-\frac{P_{u}}{P_{e x}}\right)}=1
$$

Solve for $P_{u}$

$$
P_{u}=A-\sqrt{A^{2}-B}
$$

where

$$
\begin{aligned}
& A=\frac{\phi_{c} P_{n} \phi_{b} M_{n}+\phi_{b} M_{n} P_{e x}+\phi_{c} P_{n} P_{e x} C_{m x} C_{l x}}{2 \phi_{b} M_{n}} \\
& B=\phi_{c} P_{n} P_{e x}
\end{aligned}
$$

$$
\begin{aligned}
& P_{n}=31.82 \text { kips } \quad(\text { From Approach } 1 a) \\
& P_{e x}=37.7 \text { kips } \quad(\text { From Approach } 1 a) \\
& M_{n}=F_{y} S_{x}=(55)(1.161)=63.85 \mathrm{kip}-\mathrm{in} . \quad\left(M_{e} \geq 2.78 M_{y} \text { and Fully effective }\right) \\
& C_{m x}=0.85
\end{aligned}
$$

therefore

$$
\begin{aligned}
& A=\frac{(31.82)(63.85)+(63.85)(37.7)+(31.82)(37.7)(0.85)(0.216)}{2(63.85)}=36.48 \mathrm{ksi} \\
& B=(31.82)(37.7)=1199.6 \mathrm{ksi}^{2} \\
& P_{u}=36.48-\sqrt{36.48^{2}-1199.6}=25.03 \mathrm{ksi} \text { Answer }
\end{aligned}
$$

## APPROACH 2 - NOTIONAL LOAD APPROACH

## Approach 2a

Solve for $P_{n(L)}$

$$
\begin{aligned}
& P_{e x(L)}=\frac{\pi^{2} E I_{x}}{L_{x}^{2}}=\frac{\pi^{2}(29500)(1.8)}{60^{2}}=145.58 \mathrm{kips} \\
& F_{e}=\frac{P_{e x}}{A}=\frac{145.58}{1.2}=121.32 \mathrm{ksi} \\
& \lambda_{c}=\sqrt{\frac{F_{y}}{F_{e}}}=\sqrt{\frac{55}{121.32}}=0.673<1.5, \text { therefore } \\
& F_{n}=\left(0.658^{\lambda_{c}^{2}}\right) F_{y}=\left(0.658^{0.673^{2}}\right)(55)=45.5 \mathrm{ksi}
\end{aligned}
$$

$$
P_{n(L)}=A_{e} F_{n}=(1.2)(45.5)=54.6 \mathrm{kips} \quad \text { (Fully effective) }
$$

The objective is to solve the following interaction equation for $P_{u}$

$$
\frac{P_{u}}{\phi_{c} P_{n(L)}}+\frac{M_{u}}{\phi_{b} M_{n}} \leq 1
$$

Using similar procedures as Approach $1 c$, the interaction equation above becomes

$$
\frac{P_{u}}{\phi_{c} P_{n(L)}}+\frac{C_{m x} C_{l x} P_{u}}{\phi_{b} M_{n}\left(1-\frac{P_{u}}{P_{e x}}\right)}=1
$$

Solve for $P_{u}$

$$
P_{u}=A-\sqrt{A^{2}-B}
$$

where

$$
\begin{aligned}
& A=\frac{\phi_{c} P_{n(L)} \phi_{b} M_{n}+\phi_{b} M_{n} P_{e x}+\phi_{c} P_{n(L)} P_{e x} C_{m x} C_{l x}}{2 \phi_{b} M_{n}} \\
& B=\phi_{c} P_{n(L)} P_{e x} \\
& P_{e x}=37.7 \text { kips (From Approach 1a) } \\
& M_{n}=63.85 \text { kip-in. (From Approach 1c) } \\
& C_{l x}=0.216 \quad \text { (From Approach 1c) } \\
& C_{m x}=0.85
\end{aligned}
$$

therefore

$$
\begin{aligned}
& A=\frac{(54.6)(63.85)+(63.85)(37.7)+(54.6)(37.7)(0.85)(0.216)}{2(63.85)}=49.11 \mathrm{ksi} \\
& B=(54.6)(37.7)=2058.4 \mathrm{ksi}^{2}
\end{aligned}
$$

$$
P_{u}=49.11-\sqrt{49.11^{2}-2058.4}=30.31 \mathrm{ksi} \quad \text { Answer }
$$

## Approach 2b

From Eq. (5.8), $K_{x}>1.7$ therefore $\xi=1 / 240$. Since this is the same $\xi$ value used in Approach $2 a$, the resulting $P_{u}$ would also be the same.

## Approach 2c

The objective is to solve the following interaction equation for $P_{u}$

$$
\frac{P_{u}}{\phi_{c} P_{n(L)}}+\frac{M_{u}}{\phi_{b} M_{n}} \leq 1
$$

Using the same procedures as Approach $1 c$, the interaction equation above becomes

$$
\frac{P_{u}}{\phi_{c} P_{n(L)}}+\frac{C_{m x} C_{l x} P_{u}}{\phi_{b} M_{n}\left(1-\frac{P_{u}}{P_{e x} *}\right)}=1
$$

Solve for $P_{u}$

$$
P_{u}=A-\sqrt{A^{2}-B}
$$

where

$$
\begin{aligned}
& A=\frac{\phi_{c} P_{n(L)} \phi_{b} M_{n}+\phi_{b} M_{n} P_{e x} *+\phi_{c} P_{n(L)} P_{e x} * C_{m x} C_{l x}}{2 \phi_{b} M_{n}} \\
& B=\phi_{c} P_{n(L)} P_{e x}^{*} \\
& \left.P_{n(L)}=54.6 \text { kips (From Approach } 2 a\right) \\
& M_{n}=63.85 \text { kip-in. } \quad \text { (From Approach } 1 c \text { ) }
\end{aligned}
$$

$$
\begin{aligned}
& C_{l x}=0.216 \quad(\text { From Approach } 1 c) \\
& C_{m x}=0.85
\end{aligned}
$$

The only parameter that is effected by making the flexural stiffness reduction is $P_{e x} *$ used in the above equations for determining $A$ and $B$. From Eq. (5.9)

$$
\begin{aligned}
& E I_{x}^{*}=0.9 E I_{x}=(0.9)(29500)(1.8)=47790 \mathrm{kip}-\mathrm{in}^{2} \\
& P_{e x}^{*}=\frac{\pi^{2} E I_{x} *}{\left(K_{x} L_{x}\right)^{2}}=\frac{\pi^{2}(47790)}{((1.965)(60))^{2}}=33.93 \mathrm{kips}
\end{aligned}
$$

therefore

$$
\begin{aligned}
& A=\frac{(54.6)(63.85)+(63.85)(33.93)+(54.6)(33.93)(0.85)(0.216)}{2(63.85)}=46.93 \mathrm{ksi} \\
& B=(54.6)(33.93)=1852.6 \mathrm{ksi}^{2} \\
& P_{u}=46.93-\sqrt{46.93^{2}-1852.6}=28.23 \mathrm{ksi} \text { Answer }
\end{aligned}
$$

Compare the results with the finite element solution

| Approach | $P_{u}$ | $\frac{P_{u}-P_{F E M}}{P_{F E M}} \times 100 \%$ |
| :---: | :---: | :---: |
| $1 a$ | 31.82 | $3.85 \%$ Unconservative |
| $1 c$ | 25.03 | $18.31 \%$ Conservative |
| $2 a$ and $2 b$ | 30.31 | $1.08 \%$ Conservative |
| $2 c$ | 28.23 | $7.87 \%$ Conservative |

## Computer Programs

Four computer programs have been developed to carry out the extensive parametric studies which involved the analysis and the design of cold-formed steel members and structures conducted in this research project. Description for each of these computer programs, and their User's Guide are as follows:

CUEWA Effective Width Approach: is a computer program designed to compute the nominal flexural strength $M_{n}$ and the nominal axial strength $P_{n}$ of coldformed steel sections using two approaches: the AISI (1996) method, and the Intergraded Distortional Buckling method given by Schafer and Peköz (1999).

CUPBF Plate Buckling and Free Vibration: is a computer program designed to solve three types of problems involving the eigenvalue analysis: plate elastic buckling, free-vibration, and free-vibration with initial in-plane stresses. The program uses the finite element method with four-node rectangular thin plate elements. Various boundary conditions and perforations can be applied.

CUTWP Thin-Walled Section Properties: is a computer program designed to compute cross section properties and overall elastic buckling loads of thin-walled members.

CUSRF Semi-Rigid Frame Analysis: is a computer program designed to perform first-order elastic, second-order elastic, and elastic buckling analyses of twodimensional semi-rigid frames.

# CUEWA 

## Effective Width Approach

Developed by:<br>Andrew Sarawit

The Rack Mamufactures Institute
The American Iron and Steel Institute

## Introduction

- CUEWA is a computer program designed to compute the nominal flexural strength, $\mathrm{M}_{\mathrm{n}}$ and the nominal axial strength, $\mathrm{P}_{\mathrm{n}}$ of cold-formed steel sections using two approaches: the AISI (1996) method, and the Intergraded Distortional Buckling method given by Schafer and Peköz (1999).
- The program can be obtained at http://ceeserver.cee.cornell. edu/tp26, available as both a stand-alone windows application and a Matlab application.
- To run the Matlab version simply change the Matlab current directory to the installed CUEWA directory then type cuewa at the Matlab command line.
- Matlab version of this program should not be installed in a directory path name that contain spaces.

> Incorrect: c:\Program Files $\backslash C U E W A \_M A T L A B$ Correct: c: $\backslash$ Program_Files $\backslash C U E W A \_M A T L A B ~$

- The program is best viewed on a $1024 \times 768$ pixels screen resolution.

## Getting Started with CUEWA

- The following figure shows the layout of the CUEWA program, which consists of 4 components, descriptions of these components are as follows:

## Input Data:

- Define the nodal x - and y -coordinates in Noda Data. Node numbering is defined automatically as the row index number.
- Define the first and second node numbers forming the element in Element Data.
- The thin-walled section could be either an open section or a closed section.
- Elements forming the cross section should not be refined.

- Elements with intermediate stiffeners are not applicable.
- The local and distortional buckling stress could be obtained by using the Finite Strip Method program CUFSM.
- Local and distortional buckling stresses are not needed for the AISI method.
- If the section does not have a distortional buckling mode, simply provide a very high value, such that the distortional buckling mode will not be the controlling buckling stress in the IDB method.
- The inelastic flexural reserve capacity is not considered for both the AISI method and the IDB method
- A single median radius is used for all corners.
- Arithmetic operators,,+- , and / can be used in the edit text fields.
- The units chosen must be self-consistent.

## Output Data:

- The computed data are displayed in this area.
- When the nominal flexural strength option is selected, the location of the effective section neutral axis, NA, is computed. The value is the vertical distance of this axis from the origin.
- When the nominal axial strength option is selected, the location of the effective sections centroid is computed. The $\mathrm{x}_{\mathrm{c}}$ and $\mathrm{y}_{\mathrm{c}}$ are the centriod coordinates with respect to the origin.
- $f_{c r}$ is the controlling buckling stress, and $R_{d}$ is the reduction factor for the distortional buckling. A detailed definition of these values can be found in Schafer, B.W., and Peköz, T.P., (1999).

## Push Buttons

- Saving the file for future use or loading an existing file is possible by use of the Save As ... button or Open... button.
- A report is automatically generated when the file is saved. The created text file has the ewa extension.
- Use the AISI method button to compute the section strength according to the AISI (1996) Specification.
- Use the IDB method button to compute the section strength on the basis of the Intergraded Distortional Buckling method given by Schafer and Peköz (1999).
- Procedures of both methods are similar except that the IDB method integrates the distortional buckling into the unified effective width approach and an alternative approach for calculating the effective width of the web introduced by Schafer (1997) is used.
- Verification examples from the $\operatorname{AISI}$ (1996) are given in the example folder.

## Effective Section Plot:

- This area is used to display the effective section, which is in blue. The red color shows the region of the ineffective area of the section.
- The yellow line is the effective section neutral axis in the case of nominal flexural strength, and is the effective section centroid in the case of nominal axial strength.

The American Iron and Steel Institute

## Introduction

- CUPBF is a computer program designed to solve three types of problems involving the eigenvalue analysis: plate elastic buckling, free-vibration, and free-vibration with initial in-plane stresses.
- The program uses the finite element method with four-node rectangular thin plate elements. Various boundary conditions and perforations can be applied.
- The program can be obtained at $\underline{h t t p}: / /$ ceeserver cee.cornell. edu/tp26, available only as a Matlab application.
- To run the Matlab version simply change the Matlab current directory to the installed CUPBF directory then type cupbf_post at the Matlab command line.
- Matlab version of this program should not be installed in a directory path name that contain spaces

```
Incorrect: c:\Program Files\CUPBF_MATLAB
Correct: c:\Program_Files\CUPBF_MATLAB
```

- The program is best viewed on a $1024 \times 768$ pixels screen resolution

## Plate Elastic Bucking

The $m$-file that performs the finite element elastic buckling analysis is called "cupbf.m". This m -file requires 10 input parameters and returns 1 output. To run the analyses make the call to the $m$-file cupbf by:

APRATIOS = cupbf('filename',coord,ends, t , E,v, fixity, req_modes, cload,dload);
Description of the input and output parameters are as follows:
a) Give the 'filename' which will be the filename.mat containing the data results from the analysis. The results may be viewed later by using the post-processor.
b) Define coordinates ["coord"] of all nodes. Since this is a two-dimensional problem the first and second columns contain x - and y -coordinates of the nodes. Therefore, ["coord"] will be a
two-column matrix with numbers of node rows. Node numbering is defined automatically as the row index number.
c) Give the node connectivity matrix ["ends"]. This matrix defines which nodes are connected to each other. It will be a four column matrix containing indices to the corner points, given counter clockwise order. The number of rows in this matrix is equal to the number of elements. Element numbering is defined automatically as the row index number.

The next three inputs [" t "], ["E"] and ["v"] are all vector matrixes. The size of the vector matrix is equal to the number of elements and element numbering is defined automatically as row index number.
d) Define the element thickness in [" $t$ "].
e) Define the element material elastic modulus, Young's Modulus in ["E"].
f) Define the element material Poisson's ratio in ["v"].
g) Establish support conditions ["fixity"] by first defining transverse d.o.f. $x, y, z$ and then rotation d.o.f. about $x$-axis, $y$-axis, $z$-axis of each node. A free degree of freedom will have a value of NaN while a supported degree of freedom will have a value of 0 . ["fixity"] is a sixcolumn matrix with numbers of node rows. Node numbering is defined automatically as the row index number.
h) Request the maximum number of eigenvalue in ["req_modes"].
i) Define the in-plane concentrated load in ["cload"] where we give the numerical value of the force in $x$ and $y$ direction at each node. Nodes that do not have concentrated load should be defined with a value of zero. ["cload"] is a two-column matrix with numbers of node rows. Node numbering is defined automatically as the row index number.
j) Define the in-plane distributed load in ["dload"] where we give the numerical value of the distributed stress in $x$ and $y$ direction at each node. Nodes that do not have distributed load should be defined with a value of NaN . The distributed stress will be linearly interpolated between the adjacent nodes. ["dload"] is a two-column matrix with numbers of node rows. Node numbering is defined automatically as the row index number.

Instead of giving these input parameters manually a preprocessor function "cupbf_pre.m" is also provided.
$(c o o r d, e n d s, t, E, v, f i x i t y, c l o a d, d l o a d, p)=$ cupbf_pre $(w x, w y, n x, n y, t, E, v, p)$;
This function generates a default input parameter for a rectangular plate automatically by defining the width ['wx'], length ['wy'], the number of elements in the width ['nx'], the number of elements in the length ['ny'], ['t'], ['E'] and ['v'], all as a scalar.

Once all the inputs are defined the output eigenvalue ["APRATIOS"] and the result file "filname.mat" can be generated by simply running the function "cupbf.m" with the input parameters in the parentheses as shown. The results of running this analysis can be viewed by running the post-processor program "cupbf_post.m".

Figure 1 CUPBF Post-Processor

The following is a detailed example of how to use the elastic buckling analysis option in the CUPBF program. The objective is to verify the plate buckling coefficients for various types of boundary conditions. The theoretical elastic buckling stress for a plate may be expressed as

$$
\begin{equation*}
F c r=k \frac{\pi^{2} E}{12\left(1-v^{2}\right)(b / t)^{2}} \tag{1}
\end{equation*}
$$

where $E$ is the modulus of elasticity, $v$ Poisson's ration, $b / t$ the width to thickness ratio and $k$ the plate buckling coefficient depending on type of stress, edge support conditions, and length to width ratio of the plate. Values of k for long plates and various boundary conditions are shown in Table 1 as given by AISI (1996). Consider the case (a) in Table 1 a rectangular compression plate with an idealized simply supported condition for all four edges. Dimensions of the rectangular plate in the study are $6 \times 24 \mathrm{in}$. and thickness, $\mathrm{t}=0.1 \mathrm{in}$. The material model used is $E=29500$ ksi and $\nu=0.3$.

The critical buckling stress is calculated from the obtained eigenvalue and with the critical buckling stress known the plate-buckling coefficient can be calculated from Eq. 1. The $m$-files for all the other different types of boundary conditions given in Table 1 are also included with the program. The buckled shape, critical stress and plate buckling coefficients are summarized and compared with the given value by AISI (1996) in Table 1. It is expected that as the length to width ratio of the plate increases the $k$ obtained from the buckling analysis will converge to the given values for long plate.

## The complete $\mathbf{m}$-file ex_a.m is given here:

```
8 Define the plate properties
t = 0.1; E = 29500; v = 0.3; wx = 6;wy = 4*wx; nx = 8; ny = 4*nx; req_modes = 1;
% Use the preprocessor function to generate the default input parameter
[coord,ends,t,E,v,fixity,cload,dload] = cupbf_pre(wx,wy,nx,ny,t,E,v);
% Define the apply distributed stress and the boundary condition by modifying
% the input parameters generated from cupbf_pre.m
nnodes = size(coord,1);
for j = 1:nnodes
    if coord(j,1) == 0 | coord(j,1) == wx
        fixity(j,[3 4]) = 0;
    end
    if coord(j,2)==0
                fixity(j,[3 5]) = 0;
                dload(j,2) = 1;
    elseif coord(j,2) == wy
                fixity(j,[3 5]) = 0;
                dload(j,2) = -1;
    end
end
fixity(149,[1 2 6]) = 0;
% Perform the Elastic buckling Analysis
APRATIOS = cupbf('ex_a',coord,ends,t,E,v,fixity,req_modes,cload,dload)
% Calculate the plate buckling coefficients
k = APRATIOS*12* (1-0.3^2)* (6/0.1)^2/(pi^2*29500)
```

Table 1 Values of Plate Buckling Coefficients

Table 1 (cont.) Values of Plate Buckling Coefficients

## Plate Free-Vibration

The m-file that performs the finite element free-vibration analysis is called "cupbf.m". This m-file requires 9 input parameters and returns 1 output. To run the analyses make the call to the m-file plate_bucking by:

ARRATIOS = cupbf('filename', coord,ends,t, E, v, fixity, req_modes,p);
Description of the input parameters is the same as previously given except for an additional vector matrix, the element material mass per unit volume ["p"]. The size of the vector matrix is equal to the number of elements and element numbering is defined as from first row to last row respectively. The output eigenvalue ["APRATIOS"] is the square of the natural frequency.

The following is a detailed example of how to use the free-vibration analysis option in CUPBF program. The consistent mass matrix of the four-node rectangular element is used to test a free-vibration problem of a simply supported square plate. Sixteen elements are used here to modal the plate. The results for the six fundamental natural frequencies together with the exact values are given in Table 2. It appears that this element serves as a good tool for dynamic analysis. The theoretical solution for the natural frequencies may be expressed as

$$
\omega_{m n}=\pi^{2} \sqrt{\frac{D}{\rho h}}\left(\frac{m^{2}}{l_{1}^{2}}+\frac{n^{2}}{l_{2}^{2}}\right) \text { with }(m, n) \text { being the mode number }
$$

Figure 2 Simply supported square plate free-vibration mode shapes

Table 2 Natural frequencies $\omega_{\mathrm{ij}}(\mathrm{rad} / \mathrm{sec})$ for a simply supported square plate*

|  | $\omega_{11}$ | $\omega_{12}$ | $\omega_{22}$ | $\omega_{13,}$ | $\omega_{23,}$ | $\omega_{33}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |

## The complete $\mathbf{m}$-file ex_free.m is given here:

```
8 Define the plate properties
t=0.1; E = 30e6; v = 0.3;wx = 10;wy = wx; nx = 4; ny = nx; req modes =6;
p = 0.001;
8 Use the preprocessor function to generate the default input parameter
[coord,ends,t,E,v,fixity,cload,dload,p] = cupbf_pre(wx,wy,nx,ny,t,E,v,p);
8 Define the the boundary condition by modifying the input parameters
8 generated from cupbf_pre.m
nnodes = size(coord,1);
for j = 1:nnodes
    if coord(j,1) == 0 | coord(j,1) == 10
        fixity(j,(3 4) ) = = ;
    end
    if coord(j,2) =- | coord(j,2) == 10
        fixity(j,(3 5)) = 0;
    end
end
8 Perform the Elastic buckling Analysis
APRATIOS = cupbf('ex_free',coord,ends,t,E,v,fixity,req_modes,p)
```

## Plate Free-Vibration with Initial In-plane Stress

The m-file that performs the finite element free-vibration with initial in-plane stress analysis is called "cupbf.m". This m-file requires 11 input parameters and returns 1 output. To run the analyses make the call to the m-file cupbf by:

APRATIOS $=$ cupbf ('filename', coord, ends, $\mathrm{t}, \mathrm{E}, \mathrm{v}$, fixity, req_modes, cload, dload, p);
Description of the input parameters is same as previously. The output eigenvalue ["APRATIOS"] is the square of the natural frequency.

# CUTWP 

# Thin-Walled Section Properties 

Developed by:<br>Andrew Sarawit<br>Prof. Teoman Peköz

Cold-Formed Steel Structures Research Group
School of Civil and Environmental Engineering
Cornell University

Sponsored by:
The Rack Mamufactures Institute
The American Iron and Steel Institute

## Introduction

- CUTWP is a computer program designed to compute cross section properties and overall elastic buckling loads of thin-walled members.
- The program can be obtained at http://ceeserver.cee.cornell. edu/tp26, available as both a stand-alone windows application and a Matlab application.
- To run the Matlab version simply change the Matlab current directory to the installed CUTWP directory then type cutwp at the Matlab command line.
- Matlab version of this program should not be installed in a directory path name that contain spaces.

## Incorrect: $\mathrm{c}:$ :Program Files $\backslash C U T W P$ MATLAB <br> Correct: c:\Program_Files\CUTWP_MATLAB

- The program is best viewed on a $1024 \times 768$ pixels screen resolution.

## Getting Started with CUTWP

- The following figure shows the layout of the CUTWP program, which consists of 5 components; descriptions of these components are as follows:

## Input Data:

- Define the nodal x - and y -coordinates in Noda Data. Node numbering is defined automatically as the row index number.
- Define the first and second node numbers forming the element and then the element thickness in Element Data. Element numbering is defined automatically as the row index number.
- The thin-walled section could be either an open section or a closed section.
- The shear center coordinates, warping constant, $\mathrm{B}_{1}, \mathrm{~B}_{2}$, and elastic buckling loads are not computed for closed sections.
- Sections with multiple closed loops or loops with additional element segment branches are not applicable.
- Definition of the effective unbraced length is as defined by AISI (1996); however, the effective unbraced lengths are $\mathrm{KL}_{1}$ and $\mathrm{KL}_{2}$ not $\mathrm{KL}_{\mathrm{x}}$ and $\mathrm{KL}_{\mathrm{y}}$ because the supports are defined about the principle axis.
- The ( $\mathrm{x}, \mathrm{y}$ ) axis is used to define the cross section while the $(1,2)$ axis is the cross sectional principal axis.
- If the elastic critical axial force, $\mathrm{P}_{\mathrm{e}}$, is selected, the load eccentricities from the centroid about the $x$-axis and the $y$-axis must be defined.
- If the elastic critical moment, $\mathrm{M}_{\mathrm{e}}$, is selected, additional options are given to define the axis of bending
- Axis of bending is about the principal axis $(1,2)$ not the reference axis $(x, y)$. Generally axis $(1,2)$ and ( $\mathrm{x}, \mathrm{y}$ ) may not coincide; for example, a Z-section with the web defined parallel to the $y$-axis.
- Arithmetic operators,,+- , and / can be used in the edit text fields.
- The units chosen must be self-consistent.

## Section Properties:

- The computed cross section properties are displayed in this area.
- Moment of inertia values are computed with respect to the cross sectional centroid.
- The centroid and shear center coordinates are given with respect to the origin.
- Definition of $B_{1}$ and $B_{2}$ are similar to the AISI Eq. C3.1.2-14 but here it is computed with respect to the principal axis $(1,2)$.

$$
\begin{aligned}
& \mathrm{B}_{1}=\frac{1}{\mathrm{I}_{1}} \int_{\mathrm{A}} \mathrm{x}_{2}\left(\mathrm{x}_{1}{ }^{2}+\mathrm{x}_{2}{ }^{2}\right) \mathrm{dA}-2 \mathrm{x}_{\mathrm{o} 2} \\
& \mathrm{~B}_{2}=\frac{1}{\mathrm{I}_{2}} \int_{\mathrm{A}} \mathrm{x}_{1}\left(\mathrm{x}_{1}{ }^{2}+\mathrm{x}_{2}{ }^{2}\right) \mathrm{dA}-2 \mathrm{x}_{\mathrm{ol}}
\end{aligned}
$$

## Elastic Buckling Load:

- Use the slider bar to observe the different buckling modes.
- For axial force, the first buckling mode is generally the most critical.
- Negative buckling load values are possible, this simply means that the axial force is in tension or the bending moment is in the opposite direction from the positive sign convention given in the following figure:

## Push Buttons

- Saving the file for future use or loading an existing file is possible by use of the Save As... button or Open... button.
- A report is automatically generated when the file is saved. The created text file has the twp extension.
- Use the Apply button to compute the cross section properties.

## Display and Plot Options:

- This area is used to display and control the plots of the cross section.
- Judgment should be made when viewing the buckled shape. Any scalar multiple of the buckled shape (eigenvector) is also a solution to this eigenvalue buckling problem.
- Node \& Segment option is useful for when defining the cross section.
- Axis $(1,2)$ option is useful when identifying the principle axis.
- Axis ( $\mathrm{x}, \mathrm{y}$ ) is displayed at the cross sectional centroid and is used to compute $I_{x}, I_{y}$, and $I_{x y}$. It is not the reference axis ( $x, y$ ) which is at the origin and is used to define geometry of the cross section.

# CUSRF 

Semi-Rigid Frame Analysis

Developed by:<br>Andrew Sarawit

Prof. Teoman Peköz

Cold-Formed Steel Structures Research Group
School of Civil and Environmental Engineering
Cornell University

Sponsored by:
The Rack Mamufactures Institute
The American Iron and Steel Institute

Version 2003

## Introduction

- CUSRF is a computer program designed to perform first-order elastic, secondorder elastic, and elastic buckling analyses of two-dimensional semi-rigid frames.
- The program can be obtained at http://ceeserver.cee.cornell.edu/tp26, available as both a stand-alone windows application and a Matlab application.
- To run the Matlab version simply change the Matlab current directory to the installed CUSRF directory then type cusrf at the Matlab command line.
- Matlab version of this program should not be installed in a directory path name that contain spaces.

$$
\begin{aligned}
& \text { Incorrect: } \mathrm{c}: \backslash \text { Program Files } \backslash \text { CUSRF_MATLAB } \\
& \text { Correct: } \mathrm{c}: \backslash \text { Program_Files } \backslash C U S R F \_M A T L A B ~
\end{aligned}
$$

- The program is best viewed on a $1024 \times 768$ pixels screen resolution.
- If you are using Windows XP there could be some display problems. Possible workarounds that you can do is to change to the "Windows Classic Style" mode. This can be done as follows

1) Choose the Control Panel from the Start Menu.
2) Choose Appearance and Themes from the Control Panel.
3) Choose the Display Control Panel Icon from the Appearance and Themes menu.
4) Select the Appearance Tab. Then, under Windows and Buttons, change the display to Windows Classic style.

## Getting Started with CUSRF

- The figure in the following page shows the layout of the CUSRF program, which consists 5 menu bars, descriptions of these menus are as follows:

## File Menu:

- Saving the file for future use or loading an existing file is possible by use of the Save As ... button or Open... button.

## Frame Menu:

Frame $>$ Geometry

- The geometry of the frame is simply defined by giving the dimensions of the width of bays and the height of stories.
- The number of beam elements to be used in each bay and each story is defined in "Number of elements/bay" and "Number of elements/story"
- Frame geometric imperfection can be defined in "Story out-of-plumbness" (units: length/length) by giving the inter story out-of-plumbness for each story level. If the value is same for all stories, simply select the "All stories" option.
- Arithmetic operators,,+- , and / can be used in the edit text fields.
- The units chosen must be self-consistent.

## Frame > Connection Stiffness

- The connection stiffness can be defined as semi-rigid, rigid or pin.
- k is the constant connection stiffness (units: moment/rad)

## Frame $>$ Load Conditions

- Uniformly distributed gravity load (units: force/length) applied on each bay can be defined in "Gravity Loads". If the value is same for all bays, simply select the "All stories \& Bays" option.
- Horizontal load (units: force) applied on each story level can be defined in "Horizontal loads". If the value is same for all stories, simply select the "All stories" option.

## Frame $>$ Section Properties

| 4) Section Properties |
| :--- |
| Column Section Properties Beam Section Properties <br> A: $\sqrt{0.84}$  <br> Iz: $\sqrt{1.418}$  <br> As: $\sqrt{0.84}$  <br> E: $\sqrt{29500}$  <br> v: $\sqrt{0.3}$ 1.337 <br> Iz: $\sqrt{5.564}$ <br> As: $\sqrt{1.337}$ <br> E: $\sqrt{29500}$ <br> v. $\sqrt{0.3}$ |

- Similar to a typical pallet rack structure, a single column section and a single beam section are used for the entire frame.
- $A_{s}$ is the equivalent shear area used to calculate the shearing deformation. Define this value as "int" (infinity) to disregard the transverse shear deformation.

## Frame $>$ Sidesway Uninhibited or Inhibited

- The frame can be defined either as a sidesway uninhibited frame or a sidesway inhibited frame by using the frame menu.

## Analysis Menu:

- The analysis type, which will be performed, can be selected from this menu. To execute the analysis simply press the Run button.
- Choose a node number to be monitored. The results for this node will be shown in Report > Summary data
- Define the number of buckling modes to be computed "Number of modes" when the elastic buckling analysis is selected
- Defined initial load proportion factor "LPFin" and the acceptable equilibrium tolerance "etol" when the second-order elastic analysis is selected.
- The second-order elastic analysis is terminate when the maximum value of the load proportional factor "LPFmax" or the maximum number of increments "Number of INC" is reach.
- The constant arc length method is used in the second-order elastic analysis

## Plot Menu:

- This menu is used to control the plots options.
- Use the slider bar located at the bottom left portion of the program to observe the different increments or the different buckling modes.
- Use "Scale" located at the bottom left portion of the program to change the magnitude of the plot

## Report Menu:

- This menu is used to display the generated input data, output data and summary data.
- A report containing these data is also automatically generated when the file is saved. The created text file that contains the input data has the in extension, output data has the out extension, and summary data has the sum extension.
